1. Introduction

Considering the current environmental concerns towards the creation of eco-friendly materials that are entirely or partially biobased, the use of natural fibres as reinforcements in biocomposites in sectors like automotive, building and construction or sports is a great opportunity and has been the subject of various recent scientific reviews (Bourmaud, Shah, Placet, & Baley, 2018; Lau, Hung, Zhu, & Hui, 2018; Mohanty, Pin, & Misra, 2018; Sanjay et al., 2018; Pickering, Aruan Efendy, & Le, 2016; Yan, Chouw, & Jayaraman, 2014; Müssig, 2010). Natural fibres have many advantages compared to synthetic fibres, such as their renewability, biodegradability, wide availability and low cost associated with low density and high specific mechanical properties. However, the implementation of these materials in industrial applications is limited by the low thermal and dimensional stability of natural fibres, especially in humid conditions, as well as poor interfacial adhesion with several polymer matrices (Baley, Le Duigou, Bourmaud, & Davies, 2012; Garat, Le Moigne, Corn, Beauprè, & Bergeret, 2020; Khalidi, Bouziane, Vivet, & Bougerara, 2019; Le Duigou, Bourmaud, Balnois, Davies, & Baley, 2012; Le Duigou et al., 2017). The fibre / matrix interface plays a key role in stress transfer within biocomposite materials and their resulting mechanical performance. The main difficulty comes from the polar and hydrophilic character of lignocellulosic fibres considering their global biochemical composition and surface chemistry, whereas the thermoplastic polymer matrices often display a hydrophobic and apolar character (Bismarck et al., 2002; Faruk, Bledzki, Fink, & Sain, 2012).

To tackle these fibre / matrix compatibility issues, a wide panel of chemical and physical modifications of natural fibre surfaces have been reported in the literature (Le Moigne, Otazaghine, Corn, Angellier-Coussy, & Bergeret, 2018; Lee, Delille, & Bismarck, 2011; Mohanty, Misra, & Drzal, 2001; Zafeiropoulos, 2011). For example, coupling agents such as MAPP or MAPE were used in biocomposites to create chemical bonds between natural fibres and polyolefins (Elshabagy, Steuernagel, & Ziegmann, 2009; Lu, 2000; Mohanty, Nayak, Verma, & Tripathy, 2016; Park, Quang, Hwang, & Lawrence DeVries, 2006). Another strategy mostly used in synthetic composites consists of deposition of nanoparticles on fibre surfaces. This concept is directly inspired from naturally occurring composites such as bones, shells and

teeth which show hierarchical nanoscaled structures with amazing mechanical behaviour (Gao, Ji, Jager, Arzt, & Fratzl, 2003; Gupta et al., 2006). The design of bio-inspired hierarchical composites involves for instance the development of hierarchical fibres by the deposition of carbon nanotubes, ZnO nanowires, nanoclays, cellulose nanocrystals onto carbon, glass or natural fibres (Asadi, Miller, Singh, Moon, & Kalaitzidou, 2017; Karger-Kocsis, Mahmood, & Pegoretti, 2020; Asadi, Miller, Sultana, Moon, & Kalaitzidou, 2016; Karger-Kocsis, Mahmood, & Pegoretti, 2015; Saba, Jawaid, & Asim., 2016; Sharma et al., 2014; Yang, Han, Nie, & Wang., 2020). The purpose is to take advantage of nano-objects at the interphase to achieve local reinforcement and enhance the mechanical interlocking between fibres and matrix (Daniel Wagner, 2002; Hughes, Morley, & Jackson., 1980).

Some studies focused on fully bio-based nanostructuration of natural fibres with the use of bacterial cellulose (BC), cellulose nanofibrils (CNF) or cellulose nanocrystals (CNC). The deposition of BC and CNF on sisal, hemp and flax fibre surfaces was investigated in several studies (Blaker, Lee, & Bismarck, 2011; Fortea-Verdejo, Lee, Zimmermann, & Bismarck, 2016; Juntao, Pommet, Mantalaris, Shaffer, & Bismarck, 2007; Juntao et al., 2008; Lee, Bharadia, Blaker, & Bismarck, 2012; Pommet et al., 2008). Lee et al. successfully created “hairy” coated sisal fibres via their dipping in a slurry of BC for the reinforcement of PLA based bio-composites (Lee et al., 2012). The results were promising with a strong increase of the specific surface area up to 800 % compared to neat sisal fibres. Moreover, the storage modulus of the PLA / BC coated sisal fibres based biocomposite was increased by roughly 20 % compared to PLA / neat sisal fibres. However, the modification of natural fibres by bacterial cellulose requires specific conditions to control the fermentation bio-process, i.e. the culture medium, pH, temperature and especially the incubation time that can last for several days. Very few papers deal with the deposition of CNC on natural fibre surfaces. Dai and Fan worked on the deposition of CNC on hemp fibres and its effects on the fibre properties and adsorption of polyester resin, but did not study the mechanical performance of composites (Dai & Fan, 2013). Ghasemi et al. studied the process of CNF and CNC deposition on hemp and flax yarns and the resulting mechanical properties of the fibres, but did not prepare any composites with the treated yarns (Ghasemi, Tajvidi, Bousfield, & Gardner, 2018). The only works dealing with the use of CNC as interfacial modifier in bio-composites were conducted by Hajlaine et al. (Hajlaine, Kaddami, & Joffe, 2017; Hajlaine, Joffe, & Kaddami, 2018). The authors worked on the adsorption of CNC on regenerated cellulose fibre surfaces. They showed that fibres treated with CNC adsorbed two times less water than untreated fibres at RH of 64 % and exhibited an increase in the interfacial shear strength (IPSS) with an epoxy resin matrix.

In this context, the goal of this work is to modify flax fibre surfaces by nanostructuration with CNC so as to reinforce apolar polymer matrices. It has been shown in literature that the strength of the interfacial adhesion is mainly governed by the polymer surface tension, the fibre surface free energy and also to the surface chemistry and topography of the fibres (Le Duigou, Kervoele, Le Grand, Nardin, & Bale, 2014; Liotier et al., 2019). Nanostructuration with CNCS appears interesting as they display a high specific surface area of 150–800 m2/g and a high Young’s modulus of 150 GPa ± 50 GPa (Dufresne, 2017; Foster et al., 2018; Klemm et al., 2011; Moon,-Martini, Nair, Simonson, & Youngblood, 2011). Moreover, Khoshkava and Kamal found a total surface free energy of CNC γ_{OCN} = 68.9 mJ/m², being characterized by a predominant dispersive component, i.e. γ_{D,CNC} = 40.9 mJ/m² against γ_{P,CNC} = 28.0 mJ/m² for the polar component (Khoshkava & Kamal, 2013), due to its highly crystalline and (almost pure) cellulose structure. This characteristic could be very interesting to enhance the interfacial adhesion with apolar polymer matrices such as polypropylene (PP). Moreover, our previous work that focused on the adsorption mechanisms of CNC and xyloglucan (XG) on flax fibre surfaces highlighted the creation of an extensible network XG/CNC on the surface of fibres (Doineau et al., 2020). Indeed, XG displays strong affinities with cellulosic surfaces via hydrogen bonds and van der Waals interactions, which stimulated researchers to create green materials such as XG/cellulose aerogels and films (Cerclier et al., 2011, 2013; Jaafar et al., 2020; Jean, Heux, Dubreuil, Chambat, & Cousin, 2009; Sehaqui, Zhou, & Berglund, 2011). We hypothesize that the deposition of such XG/CNC complex on natural fibres could be of interest for composite applications by providing an expended interphase region with modified interfacial adhesion and enhanced mechanical performance.

This work will focus on the surface modification of short flax fibres by the adsorption of cellulose nanocrystals (CNC) and xyloglucan (XG), and the resulting interfacial adhesion and mechanical behaviour of PP / flax biocomposites prepared by extrusion and injection moulding. The coupling agent maleic anhydride grafted polypropylene (MAPP) was also incorporated in some biocomposites to provide chemical interactions and improve the compatibility between the PP matrix and (modified) flax fibres (Mohanty et al., 2016; Park et al., 2006). Wettability tests on CNC and XG/CNC modified flax fibres, and mechanical tests on bio-composites at macro- and microscopic length scales were performed. In addition, possible changes in microstructure such as crystallinity, fibre size and shape distribution, which could also influence the final mechanical performances of the materials, were analysed.

2. Materials and methods

2.1. Materials

Flax fibre bundles of average length 2.24 mm and width 110 μm (initial aspect ratio around 20) were supplied by Fibres Recherche Développement (Troyes, France). Their biochemical composition was characterized according to van Soest method (standards NF EN ISO 13,906 and NF V18-122): cellulose (79.7 ± 1.7 wt%), hemicelluloses (5.6 ± 1.0 wt%), lignin (2.8 ± 0.3 wt%), soluble (11.2 ± 0.5 wt%) and ash (0.7 ± 0.3 wt%). Polypropylene (PP), grade PPH 9020, homopolymer, was purchased from Total Petrochemicals (Meltin point =165 °C; Density 0.905 g/cm³). Maleic anhydride-grafted polypropylene (MAPP) OREVAC CA100 was purchased from Arkema (MA content = 1%; Meltin point =167 °C). Cellulose nanocrystals (CNC) were obtained by acid hydrolysis of wood pulp and provided in spray-dried powder by CelluForce (Quebec, Canada). CNC lateral dimensions: 2–5 nm; CNC length: 50–110 nm; CNC surface charge density: 0.023 mmol/g; Crystalline fraction: 0.88. Xyloglucan (XG) Glyloid 6 C was obtained from tamarind seed gum and purchased from DSP Goky Food & Chemical. M_w = 840 000 g/mol; M_w/M_s = 1.24; R_g 72 nm. Monosaccharide composition: glucose 50.7 %; xylose: 31.7 %; galactose 16.0 %; arabinose 1.6 %.

2.2. Flax fibres modification by CNC and XG

Cellulose nanocrystals (CNC) and xyloglucan (XG) were adsorbed on short flax fibre bundles. At first, flax fibres were modified only with CNC. A CNC suspension was prepared under stirring during 2 h (10 g of CNC in 1 L deionized water) followed by sonication (cycle 5; amplitude 50 %; 2 x 1 min) to break residual CNC agglomerates. Then, 10 g of flax fibres were added to the CNC suspension and gently stirred during 5 min to obtain a good dispersion of flax fibres within the suspension. The resulting mixture was stored at 4 °C during 24 h. The CNC modified fibres were then filtered with a Büchner system and dried at 105 °C during 2 h.

The same procedure was followed for the modification of flax fibres with both XG and CNC. In this case, XG was firstly adsorbed onto flax fibres as follows: XG suspension was prepared, i.e. 10 g of XG added gradually in 1 L deionized water with a vortex mixer, at 50–60 °C during few hours. Then, 10 g of flax fibres were added in the XG solution and gently stirred during 5 min to obtain a good dispersion of flax fibres within the solution. The resulting mixture was stored at 4 °C during 24 h.
The XG modified fibres were then filtered with a Büchner system and dried at 105 °C during 2 h. These fibres were then modified with CNC following the procedure described above.

The resulting CNC and XG/CNC modified flax fibres, named flax_CNC and flax_XG/CNC respectively, were stored in a conditioning room at 23 °C and 50 % relative humidity. Note that more details about sorption isotherms and localization of XG and CNC on flax fibres can be found in our previous work (Doineau et al., 2020). Based on this study, the adsorbed amounts of XG or CNC onto flax fibre surfaces were estimated around 2 wt% (20 mg / g fiber).

2.3. Surface free energy of flax fibres

As flax fibre bundles are dispersed and individualized in the matrix during composite processing, elementary flax fibres extracted from an unidirectional flax woven fabric 300 g / m² (FRD, France) were used for these experiments, and modified with CNC and XG/CNC following the same procedure described in section 2.2. The tensiometer K100SF (Krüss, GmbH) was used to perform wettability tests in different reference liquids following the Wilhelmy method (Eq. 1):

\[ F = m \cdot g = \gamma_{\text{SL}} \cdot p \cdot \cos \theta, \]  

(1)

With \( F \) the capillary force (mN) measured by the tensiometer when a single fibre is immersed in the test liquid, \( m \) (g) corresponding to the mass of the liquid meniscus formed around the immersed elementary fibre, \( \gamma_{\text{SL}} \) (mN/m) the liquid surface tension, \( p \) (µm) the fibre wetted length or perimeter and \( \theta \) (°) the static advancing contact angle between the fibre and the liquid (Pucci et al., 2017). Due to the heterogeneity of elementary flax fibre diameters, the perimeter \( p \) was determined beforehand for each tested fibre by using n-hexane (Sodipro) which has a surface tension \( \gamma_{\text{SL}} = 18.4 \) mN/m, and is a totally wetting liquid, implying that \( \cos \theta = 1 \). Then, the tested fibres were dried (16 h, 60 °C) to remove any residual n-hexane before being tested in the two other reference liquids, i.e. water, diiodomethane (Sodipro). The contact angle between the elementary flax fibre and the reference liquids was determined as follows. The elementary flax fibres (modified or not) were dipped at a velocity of 1 mm/min in a vessel containing the test liquid. The vessel was approached manually close to the fibre extremity and a fixed depth immersion was set in order to have at least 3–4 mm immersion depth. During immersion (advancing mode), the mass \( m \) is measured to obtain the contact angle. When immersion is completed, the fibre is maintained in contact with the liquid in a static position during 60 s in order to reach an “equilibrium state”. At equilibrium, the capillary force is measured and the corresponding static advancing contact angle \( \theta \) is derived from the Eq. (1). Then, the fibre is withdrawn from the liquid (receding mode). Tensiometric tests were carried out on eight samples for each type of fibre, i.e. raw flax fibres, CNC and XG/CNC modified flax fibres. Results were reproducible and gave low standard deviations.

2.4. Biocomposites processing

Blends of PP or PP / MAPP loaded at 5, 20 and 30 wt% of raw, flax_CNC or flax_XG/CNC modified fibres were compounded in a co-rotating twin-screw DSM Micro 15 extruder. The amount of MAPP was fixed at a ratio of flax fibres / MAPP (w / w) = 10. This ratio was shown to give the most efficient compatibilization between PP matrix and flax fibres (Snijder & Bos, 2006). Compositions of the different biocomposites are detailed in Table 1.

Flax fibres were dried before compounding in an oven at 80 °C during 2 h. The PP matrix or PP / MAPP pre-mix were introduced simultaneously with raw and modified flax fibres in the mixing chamber. Processing temperature was roughly 185–190 °C (setpoint temperature) with a screw speed of 50 rpm and a processing time of 10 min. The resulting biocomposite compounds were collected and pelletized to around 4 mm diameter. Then, pelleted compounds were shaped by injection moulding with a HAAKE Minijet Inject press (Thermofisher), into dumbbells type 5A specimens (ISO 157-2) for the measurement of mechanical properties. Injection conditions were \( T_{\text{inj}} = 180 °C, P_{\text{inject}} = 650 \) bar during 15 s and \( T_{\text{mold}} = 50 °C \). Biocomposite specimens were stored in a conditioning room at 23 °C and 50 % relative humidity during at least 48 h, prior to mechanical tests.

### 2.5. Differential scanning calorimetry (DSC)

Differential Scanning Calorimetry (DSC) tests were carried out using Perkin-Elmer Pyris Diamond DSC, equipped with an Intracooler II using nitrogen as purge gas. Samples of 10 mg were cut from the injection moulded specimens and placed in aluminium pans. The thermal cycle was a first heating from 10 to 200 °C, then cooling down to 10 °C and a second heating up to 200 °C with heating/cooling rates of 10 °C/min and holding times of 2 min between each step. Two samples were tested per material. Results were highly reproducible and gave low standard deviations. Melting enthalpies \( \Delta H_m \) were determined between 143 and 175 °C on the first heating ramp. The degree of crystallinity \( X_c \) (%) was calculated according to the following Eq. (2):

\[ X_c = \left( \frac{\Delta H_m}{\chi_{\text{matrix}} \times \Delta H_m^c} \right) \times 100 \]  

(2)

Where \( \Delta H_m^c \) is the melting enthalpy of 100 % crystalline PP (207 J/g) (Blaine, 2002), \( \Delta H_m \) is the melting enthalpy of the sample (J/g) and \( \chi_{\text{matrix}} \) is the weight fraction of PP or PP / MAPP within the sample.

### 2.6. Microstructural analysis by SEM

Microstructural analysis of the biocomposites was conducted on tensile specimens polished in the central zone down to 300 µm below the surface, ensuring that samples were observed in the shell/core zone (Abdennader, 2015; Bay & Tucker, 1992). These polished samples were observed by Scanning Electron Microscopy SE (FEI Quanta 200) and cartographies of 4 mm x 4 mm consisting of 16 SEM images were built using the software Aztec® (Oxford Instruments). All the SEM observations were made on samples sputter coated with carbon using a BALZERS CED 030 in order to avoid any degradation. Micrographs were obtained under high vacuum at acceleration voltage 12.5 keV. Based on cartographies, fibre size and shape distributions were analysed with the software AphelionTM V.4.3.2 (ADClis and Amerinex Applied Imaging Inc.), which automatically detects the outlines of the fibres present on the pictures. Fibre length (L) and width (W) were determined based on the maximum and minimum Feret’s diameters with roughly 1300 fibres per cartography. The fibre shape is defined by its aspect ratio (L/W), i.e. the ratio between the maximum and the minimum Feret’s diameter. Overlapped fibres were excluded from the counts. Because of the picture resolution (0.67 µm/pixel), the particles with the maximum size smaller than 335 µm² (corresponding to cell wall fragments) were not considered in the fibre size and shape distributions. The number weighted and surface weighted fibre aspect ratio (L/W) distributions were established.
2.7. Tensile properties

Tensile properties of the biocomposites were measured with a Zwick TH 010 testing machine equipped with an extensometer Zwick “clip-on” for the determination of the Young’s modulus (ISO 527 standard). The displacement speed of the crosshead was 1 mm/min for the determination of the Young’s modulus and 10 mm/min for the determination of the ultimate tensile properties (ultimate strength, elongation at break and work of rupture). Five samples per material were tested and the standard deviations are given for each of the mechanical properties.

2.8. In situ micro-mechanical tensile SEM experiments

The SEM was equipped with a tensile stage (DEBEN microtest, maximum load 5 kN) to analyse interfacial failure mechanisms. Direct observations of the crack propagation were conducted at a displacement maximum load 5 kN) to analyse interfacial failure mechanisms. Direct observations of the crack propagation were conducted at a displacement maximum load 5 kN) to analyse interfacial failure mechanisms. Direct observations of the crack propagation were conducted at a displacement maximum load 5 kN) to analyse interfacial failure mechanisms. Direct observations of the crack propagation were conducted at a displacement maximum load 5 kN) to analyse interfacial failure mechanisms. Direct observations of the crack propagation were conducted at a displacement maximum load 5 kN) to analyse interfacial failure mechanisms.

3. Results and discussions

3.1. Surface free energy of flax fibres and work of adhesion

Total surface free energy $\gamma_{tot}$ of elementary flax fibre and its polar and dispersive components $\gamma_p$ and $\gamma_d$ (mJ/m²) were determined by the Owens, Wendt, Rabel and Kaelble (OWRK) approach (Owens & Wendt, 1969) knowing the respective polar and dispersive surface tensions of the testing liquids $\gamma_p$ and $\gamma_d$ (mN/m), Eq. (9):

$$\gamma_{tot} = \sqrt{\frac{\gamma_p}{\gamma_d}} \times \sqrt{\gamma_p \gamma_d} + \sqrt{\gamma_d^2}$$

(3)

Polar and dispersive surface tension values of water ($\gamma_p = 51.0$ mN/m; $\gamma_d = 21.8$ mN/m), n-hexane ($\gamma_p = 0$ mN/m; $\gamma_d = 18.4$ mN/m), diiodomethane ($\gamma_p = 2.3$ mN/m; $\gamma_d = 48.5$ mN/m) have been used. The resulting surface free energy and its dispersive and polar component values are reported in Table 2 for non-treated and treated flax fibres. It was verified beforehand that the wetted length did not change after immersion in liquids, meaning that fibre swelling did not occur, and hence this phenomenon was not considered for surface energy determination (Pucci et al., 2017). Raw flax fibres have a total surface free energy of 34.3 ± 3.2 mJ/m² with polar and dispersive components of 18.2 ± 3.0 mJ/m² and 16.1 ± 0.2 mJ/m², respectively. First, the presence of cellulose nanocrystals (CNC) at the surface of flax fibres decreases their total surface free energy to 30.9 ± 1.9 mJ/m². Its polar component is greatly decreased from 18.2 ± 3.0 mJ/m² to 12.9 ± 0.8 mJ/m² while its dispersive component is slightly increased from 16.1 ± 0.2 mJ/m² to 18.0 ± 1.1 mJ/m².

As explained in the introduction section, CNC displays predominantly dispersive character due to its crystalline and almost pure cellulosic structure. This characteristic may explain the increased dispersive character of CNC modified flax fibres. Topographical changes at the flax fibre surface due to nanocoating with CNC might also play a role. In fact, the wettability of a surface is governed by its physico-chemical interactions with test liquids but also by its surface morphology and characteristics including roughness and specific surface area (Li et al., 2021). Qian et al. obtained the same trend via the grafting of carbon nanotubes on a carbon fibre surface with a pronounced decrease of the total surface energy of the carbon fibre from 54.6 ± 1.4 mJ/m² to 38.8 ± 2.4 mJ/m² (Qian, Bismarck, Greenhalgh, Kalinka, & Shaffer, 2006). The polar part decreased strongly from 29.7 ± 1.0 mJ/m² to 1.0 ± 0.6 mJ/m² while an increase of the dispersive part from 24.9 ± 0.4 mJ/m² to 37.8 ± 1.9 mJ/m² was observed.

For the XG/CNC modified flax fibres, no changes were observed, with total surface free energy and polar and dispersive components similar to the raw flax fibres. Hemicelluloses such as xylanogluca have a pronounced polar character (Pirich et al., 2015) and could counterbalance the dispersive effect of CNC on the fibre surface free energy.

Based on the respective surface free energy of flax fibres and surface tension of the molten matrices, i.e. PP or MAPP, it is possible to predict the adhesion strength at the fibre / matrix interface. The work of adhesion ($W_a$) greatly influences the wettability of the fibres towards the matrix during processing and plays a role in the interfacial adhesion within the final biocomposite. The higher the $W_a$, the better would be the wettability and the quality of adhesion between fibres and matrix. The work of adhesion $W_a$ (mJ/m²) was calculated with Eq. (4) derived from the OWRK approach (Owens & Wendt, 1969) based on the geometric mean of dispersive and polar components of the liquid surface tension and solid surface free energy:

$$W_a = 2 \times \sqrt{\gamma_p \gamma_d}$$

(4)

And with the Eq. (5) derived from the Wu approach (Wu, 1971) based on the harmonic mean of dispersive and polar components of the liquid surface tension and solid surface free energy:

$$W_a = 4 \times \frac{\gamma_p \gamma_d}{\gamma_p + \gamma_d}$$

(5)

Surface energy / tension values of PP at various temperatures measured either by the sessile drop (low temperature) or the pendant drop (high temperature) techniques (Kwok, Cheung, Park, & Neumann, 1998; Tran, Fuentes, Dupont-Gillain, Van Vuure, & Verpoest, 2013, Fuentes et al., 2018, Khoshkava & Kamal, 2013; Schonhorn & Sharpe, 1965) have been used to determine the surface tension of PP at a temperature of 190 °C, corresponding to the processing conditions used in the micro-compounder. We considered that the evolution of the surface tension and polarity of PP and MAPP is linear over the temperature range 20–220 °C, i.e. a constant polarity ratio $\gamma_p/\gamma_d$ (0.003 for PP and 0.01 for MAPP determined at 20 °C from Fuentes et al., 2018) and a constant ratio $\gamma_p/\gamma_d$ (0.053 determined at 20 °C from Fuentes et al., 2018). On this basis, we calculated the surface tension and its polar and dispersive components for PP and MAPP at 190 °C (see Table 2). Based on our calculation, the increase in temperature decreases the total surface free energy of PP and MAPP with a surface energy thermal coefficient $k$ = -0.0495 mJ / m² °C. Note that the variations of polar and dispersive components of these polymers as a function of temperature are not well known but considering the quasi-dispersive character of...
polyolefin matrices, we expect that variations should be limited.

The work of adhesion $W_A$ between flax fibres and PP or MAPP was thus determined according to Eqs. (4) and (5), and considering the surface tension of PP or MAPP in the molten state at 190 °C and the surface energies of raw flax and flax_CNC or flax_XG/CNC fibres determined by tensiometric tests on single fibres at 20 °C given in Table 2.

Besides, the values of $W_A$ determined for flax fibres / MAPP suppose a complete migration of MAPP to the fibre / PP matrix interface during the compounding process. The resulting works of adhesion for the different systems are compared in Fig. 1.

As detailed in the materials and methods, two different approaches were used to calculate $W_A$ (mJ/m²), i.e. the OWRK approach (Eq. 4) and the Wu approach (Eq. 5). OWRK approach is widely used in the literature dealing with interfacial adhesion in composites. However, Wu assumed that the harmonic mean approach gives more consistent results for low energy system interactions, the geometric mean approach being more suitable to high energy systems like adhesives on metals (Wu, 1971). As can be seen in Fig. 1, the Wu approach gives lower work of adhesion for both PP and MAPP matrices compared to OWRK approach.

As can be seen in Table 2, the Wu approach (Eq. 5) gives lower values of work of adhesion compared to the OWRK approach (Eq. 4). This is due to the fact that the Wu approach is more suitable to high energy systems like adhesives on metals (Wu, 1971). As can be seen in Fig. 1, the Wu approach gives lower work of adhesion for both PP and MAPP matrices compared to OWRK approach.

According to Table 2, the Wu approach gives lower work of adhesion for both PP and MAPP matrices compared to OWRK approach. This is due to the fact that the Wu approach is more suitable to high energy systems like adhesives on metals (Wu, 1971). As can be seen in Fig. 1, the Wu approach gives lower work of adhesion for both PP and MAPP matrices compared to OWRK approach.

Moreover, the values of work of adhesion for PP and MAPP matrices are compared in Fig. 1.

3.2. Crystallization and microstructure of biocomposites

3.2.1. Crystallization of PP and PP / MAPP

DSC analyses were performed to study the effect of the adsorption of CNC and XG/CNC on flax fibres on the crystallization of PP and PP / MAPP. In fact, the chemical composition as well as the topography of fibre surfaces could play a role on the crystallization behaviour of polymer matrices (Girones, Vo, Haudin, Freire, & Navard, 2017; Wang, Tong, Hou, Li, & Shen, 2011). Curves of the first heating scan and cooling scan are represented in Fig. 1S of the supplementary data file for each prepared biocomposite. First, melting temperatures $T_m$ of the different biocomposites were similar, i.e. roughly 166–170 °C, indicating that the presence of CNC and XG/CNC on flax fibre surfaces did not significantly affect the melting and hence the structure of PP crystals formed.

Crystallization temperatures $T_c$ were measured during the cooling step and showed slight differences between biocomposites as shown in Table 3. PP_flax, PP_flax_CNC and PP_MAPP_flax had $T_c = 131–132$ °C, while PP_MAPP_flax_CNC and PP_MAPP_flax_XG/CNC display lower $T_c$ around 127 °C. It seems that the combination of both MAPP and CNC (or XG/CNC) induces a change in the crystallization behaviour of PP with a slight decrease of its crystallization temperature, and hence a possible delayed and/or reduced nucleation. Further isothermal crystallization analysis by DSC and polarized optical microscopy observations would be...
necessary to better depict the effect of flax fibres and their surface modification on the crystallization behaviour of PP.

PP / MAPP based biocomposites reinforced with XG/CNC modified flax fibres also showed a slight decrease in the degree of crystallinity $X_c$ from around 37.5% to 35.5% (Table 3). This can be explained by the occurrence of covalent bonds between MAPP and the hydroxyl groups present at the surface of XG/CNC assemblies. This leads to the formation of a covalent bond network of lower molecular mobility at the fibres / matrix interface that could locally hamper the crystallization of PP matrix. This phenomenon is also likely to occur with non-treated flax fibres but the higher specific surface area of CNC implies a higher amount of available hydroxyl groups at the surface of fibres, and hence possibly more covalent bonds with MAPP.

3.3. Mechanical behaviour and interfacial adhesion of biocomposites

The fibre treatments could affect the fibre size and shape distribution within the biocomposites after extrusion and injection processes, so microstructural analysis was performed to investigate this possible effect. In fact, changes in fibre morphology influence greatly the mechanical properties of composite materials. In particular, the higher the aspect ratio, the most efficient is the load transfer from the matrix to the fibres, and the higher is the stiffness and strength of the composite.

An example of 4 mm x 4 mm cartography obtained by SEM on the polished surfaces of tensile specimens is shown in Fig. 2a. All cartographies of each biocomposite polished surface are shown in Fig. 2S in the supplementary data file. A good dispersion and individualization into elementary fibres is observed for a large fraction of flax fibres for all biocomposites with the presence of small particles and also some fibre bundles having much higher diameters. Results of the fibre aspect ratio distributions weighted in number and surface are reported in Fig. 2b. Median aspect ratios are very similar for the two weighted distributions and for all biocomposites. They are ranged from 2.9 to 3.2 and from 3.4 to 3.8 for number and surface weighted distributions, respectively. This indicates that the morphology of flax fibres after biocomposite processing was not affected by the different treatments, i.e. addition of MAPP coupling agent and adsorption of CNC or XG/CNC. The obtained mechanical properties of the biocomposites should thus not be influenced by variations in fibre aspect ratio.

Concluding, fibre modifications and MAPP coupling agent did not induce any significant variations in the biocomposite microstructure in terms of fibre size and shape distributions and matrix crystallinity. We thus postulate that the mechanical behaviour of the biocomposites should primarily be influenced by variations in the interfacial adhesion brought by the treatments with CNC and XG/CNC on the flax fibre surface.

3.3. Mechanical behaviour and interfacial adhesion of biocomposites

Previously, CNC adsorption onto flax fibres has been shown to lead to better work of adhesion with the matrix, this being primarily due to increased dispersible character of the fibre surface. Moreover, the MAPP coupling agent also increases the work of adhesion thanks to its higher surface tension and polarity. Macro- and micro-mechanical tests were conducted to study the influence of the combination of the MAPP coupling agent and CNC or XG/CNC fibre treatments on the mechanical behaviour and interfacial adhesion in biocomposites at different length scales.

3.3.1. Uniaxial tensile tests

Uniaxial tensile tests were performed on biocomposites to determine their Young’s modulus $E$ as well as their tensile strength $\sigma_{\text{max}}$ and work of rupture, which are more sensitive to failure mechanisms at the fibre / matrix interface and hence interfacial modifications (Le Moigne, Otazaghine, Corn, Angellier-Coussy, & Bergeret, 2018). The results of the uniaxial tensile tests are presented in Fig. 3.

As expected, Young’s modulus (Fig. 3c) increases with the amount of flax fibres (Puch & Hopmann, 2015). No pronounced effects of the CNC and XG/CNC fibre functionalization were observed as the Young’s modulus is generally little influenced by the interfacial adhesion, especially for short natural fibre composites for which the quantity of fibre / matrix interfaces developed is limited (Le Moigne et al., 2018, Agarwal, Broutman, & Chandrashekhara., 2017). We can also observe that the presence of the MAPP coupling agent even slightly decreases the Young’s moduli of the biocomposites. It could be explained by a plasticizing effect related to the presence of MAPP within the bulk of the PP matrix that did not migrate to the fibre / matrix interface.

In contrast, pronounced variations in tensile strength (Fig. 3b) are observed for the different biocomposites depending on the interfacial modifications, either MAPP coupling agent, CNC, or XG/CNC fibre functionalizations. Without the presence of MAPP, it is obvious that the PP / flax interface is not cohesive. The increase in fibre content even results in a slight decrease of the tensile strength because of this weak interfacial adhesion. The same trend is observed for raw flax and
flax CNC fibres. On the other hand, the incorporation of MAPP appears to increase the tensile strength, especially for the highest flax fibre contents. For 30 wt% flax fibres, the tensile strength increases significantly from $36.2 \pm 0.2$ MPa to $40.4 \pm 0.5$ MPa for respectively PP_flax and PP_MAPP_flax (p-value = 0.0079 based on the statistical Mann & Whitney non-parametric U test). The novelty of our approach is the combination of MAPP with the flax fibre treatment by CNC and XG/CNC. The presence of CNC and XG/CNC on fibre surfaces has a positive effect on the tensile strength of the biocomposite. In fact, the tensile strength increases from $37.4 \pm 0.9$ MPa to $38.5 \pm 0.2$MPa and $39.3 \pm 0.3$ MPa for respectively PP_MAPP_flax, PP_MAPP_flax_CNC and PP_MAPP_flax_XG/CNC at 20 wt% flax fibres (p-values of 0.19 and 0.015, respectively, based on the statistical Mann & Whitney non-parametric U test). This shows that the combination of CNC or XG/CNC functionalizations onto flax fibres combined with the incorporation of MAPP coupling agent improves the interfacial adhesion, possibly due to increased interfibril area and preferential chemical interactions between CNC and MAPP.

The work of rupture (Fig. 3d) decreases significantly with increasing fibre content. In fact, the incorporation of flax fibres makes

![Typical uniaxial tensile curves at 20 wt% fibre content (a), tensile strength (b), Young’s modulus (c) and work of rupture (d) for the different biocomposites.](image1)

![Force - displacement curves recorded during the micro-tensile test for two notched specimens of PP_MAPP_flax, PP_MAPP_flax_CNC and PP_MAPP_flax_XG/CNC with 20 wt% flax fibres and (b) the resulting work of rupture.](image2)
biocomposite materials less ductile with much lower elongation at break as seen on Fig. 3a. The increase in tensile strength brought by interfacial modifications cannot compensate for this loss in ductility, thereby leading to a decreased work of rupture.

### 3.3.2. Micro-mechanical tensile tests

The developed in situ micro-mechanical tensile SEM test allows direct observations of crack propagation while recording force-displacement curves (Fig. 4a). This experiment could be assimilated to a pull-out test at a larger scale, i.e. several fibres and bundles are progressively extracted from the matrix during the test. These experiments were performed to better depict the effect of CNC and XG/CNC treatments on interfacial adhesion of flax / PP at the microscale. First, the PP_MAPP_flax composites break at average 233 ± 2 N, while PP_MAPP_flax_CNC and PP_MAPP_flax_XG/CNC break at higher tensile forces, respectively 262 ± 15 N and 260 ± 3 N. The strength improvement related to interfacial adhesion is thus more pronounced with the micro-mechanical tensile test, which is conducted at low tensile speed (0.1 mm/min), especially for matrices showing a strong strain rate dependency as PP (Caro et al., 2018). Besides, the quality of interfacial adhesion and its role on composite failure could also be strain rate dependent. In this regard, it was found that the relation between interfacial adhesion and impact toughness of PP / glass particles systems became less pronounced as strain rate was increased (Thio, Argon, & Cohen, 2004). Nevertheless, the authors could not conclude on the origin of this strain rate dependency, being either related to the interfacial failure mechanism itself or to the plastic strain characteristics of the polymer matrix.

Moreover, the work of rupture during crack propagation has been calculated (Fig. 4b). The biocomposites with CNC and XG/CNC modified flax fibres have higher work of rupture with an increase of 12.5 % and 21.6 %, respectively. This suggests that the presence of both XG and CNC on the flax fibres modifies the failure mechanisms in the interphase zone between fibres and matrix, leading to higher forces and elongation at break. This extensible XG/CNC network with strong interactions and increasing rupture distance was characterized in our previous work (Doineau et al., 2020) by AFM adhesive force measurements. Our results suggest that such a network can have a positive influence on the breaking strength of composite systems.

An analysis of the failure mechanisms by in situ visualization of the crack propagation has been conducted for the different biocomposites (Fig. 5 and Videos 1, 2 and 3). As regards the local fibre / matrix interfacial adhesion, behaviours are similar and characteristic of both adhesive and cohesive interfacial failures. Indeed, fibre debonding as well as fibre breakage occurs, the matrix showing mainly ductile behaviour with stretching and tearing. Nevertheless, flax fibres modified by CNC and XG/CNC change the failure pattern of the biocomposites. In the case of PP_MAPP_flax, the failure occurred through the formation of a macro-crack that propagated quasi-linearly behind the crack tip. In contrast, the crack propagation in PP_MAPP_flax_CNC and PP_MAPP_flax_XG/CNC was more uneven and occurred through the formation of numerous micro-cracks. These qualitative observations support the higher work of rupture measured for these biocomposites.

The modification of interphases by the development of hierarchical natural fibres with biopolymers and nano-reinforcements such as XG/CNC thus appears as an interesting strategy to modify failure mechanisms and enhance the strength of biocomposite materials. However, it appears that a chemical coupling between the matrix and modified flax fibres such as MAPP is needed to ensure good interfacial strength and hence better work of rupture.

### 3.3.3. Work of adhesion versus practical adhesion

Fig. 6 shows the correspondence between the work of adhesion that is only governed by physico-chemical interactions between the fibres and the matrix; and the practical adhesion that is related to interfacial strength and influenced by fibre / matrix chemical interactions, mechanical anchorage, transcrystallinity at the interphase and intra and intercellular cohesion within elementary flax fibres and bundles (Le Moigne et al., 2018).

Both plots provide evidence that the combination of interfacial modifications with (i) MAPP coupling agent that brought covalent bonds with the fibres and; (ii) hierarchical fibres functionalized by CNC or XG/CNC assemblies that modify the mechanical behaviour in the interphase zone, could improve the ultimate properties of biocomposites with higher tensile strength and more progressive local failure with higher work of rupture.

### 4. Conclusions

The interphase of PP / short flax fibre thermoplastic composites was modified by the combination of two strategies, i.e. (i) chemical coupling by MAPP and (ii) flax fibre nanostructuring with the adsorption of CNC and XG. The resulting fibres and biocomposites were characterized by wettability tests, microstructural analysis, micro-mechanical tensile tests with in situ SEM observations and uniaxial tensile tests. The presence of cellulose nanocrystals on the surface of flax fibres decreased their polar character and improved the work of adhesion with PP / MAPP matrix. Uniaxial tensile tests revealed that combining the incorporation of MAPP coupling agent and the adsorption of CNC or XG/CNC on flax fibres enhanced the strength of PP / flax biocomposites. Furthermore, the work of rupture of the materials measured by micro-mechanical tensile tests was improved by 12.5 % and 21.6 % for CNC and XG/CNC treatments, respectively. To conclude, the combination of interfacial modifications with nanostructured fibres via the adsorption of CNC and XG/CNC at their surface and the use of coupling agent MAPP that provides covalent bonds with fibres, improves the ultimate

---

properties of biocomposites, giving higher strength and work of rupture, and more progressive local failures. These results open interesting perspectives for the development of bio-based hierarchical composites with enhanced structural properties, inspired by naturally occurring structures.
