Chitosan functionalized with 2-mercaptobenzimidazole (2-MBI) (i.e. 2-MBI@Chit) shows high sorption capacity (i.e., 1.28 mmol MB g<sup>-1</sup>) for methylene blue (MB) (at pH close to 9.3). Sorption is weakly decreased (by less than 25%) by high NaCl concentration (up to 45 g L<sup>-1</sup>). The sorption (slightly endothermic) is fitted by the Langmuir equation. The kinetic profile is fitted by the pseudo-first order rate equation (PFORE): equilibrium reached within 90 min of contact. The resistance to film diffusion is minimized when setting agitation speed at 200 rpm. Dye desorption is successfully achieved (up to 94.5%) using 0.8 M HCl; desorption kinetics is little slower than the sorption step. The loss in sorption capacity at the fifth sorption/desorption cycle does not exceed 5%. Yoon–Nelson, Bohart–Adams, and bed-depth service time equations are used for analyzing the breakthrough in fixed-bed columns. At the exhaustion of the column, the sorption capacity approaches the maximum sorption capacity in batch: all the reactive groups remain accessible in dynamic sorption mode. The dye is efficiently recovered from spiked seawater and the sorption performance is depreciated by less than 16% while comparing tap water and seawater under selected experimental conditions.

## 1. Introduction

Industrial development is producing a tremendous increase in the discharge of toxic and hazardous compounds such as dyes, heavy metals, pesticides, insecticides, hydrocarbons, and pharmaceutical molecules in the environment [1]. Even at trace levels, these pollutants may have dramatic impacts on different biota due to their recalcitrant, mutagenic, and carcinogenic nature [2]. The dyeing industry is considered one of the major contributors to the contamination of natural water resources [3]. As colored aromatic compounds, their impact can be explained by

different effects: direct toxicity (carcinogenicity, mutagenicity), persistence, bioaccumulation, but also eutrophication, turbidity (which may impact aquatic flora) [4].

Industrial dyes are usually classified into three main groups considering their dissolution behavior in aqueous solutions: (a) anionic (acidic) dyes with completely negative charge due to SO<sub>3</sub><sup>2-</sup> group (i.e. direct and reactive dyes), (b) cationic (basic) dyes with completely positive charge due to protonated NH<sub>2</sub> group, and (c) non-ionic form (i.e. disperse dyes) [5]. Dyes are abundantly used in various industries such as cosmetics, medicine, plastic, paper, printing, pharmaceutical

industries, perfumery, leather, varnishes, textile, and so on. The global consumption rate was estimated close to  $10^7$  kg/year [6]. More than 400,000 tons of reactive dyes are mainly used to dye cellulosic fiber especially cotton; dyeing 1 kg of cotton produces 200 kg of wastewater containing up to 50% of dye's initial feed [7].

Persistence of these released dyed effluents and/or their decomposition products in the water bodies seriously endangers the health of different living creatures [8]. They deteriorate water quality (specification) by changing the chemical oxygen demand (COD), biological oxygen demand (BOD), total dissolved solids (TDS), total suspended solids (TSS) and ultimately result in the diminishment of photosynthesis efficiency due to an increase in the water turbidity. Additionally, dyes mostly display mutagenic and carcinogenic features [9]. Methylene blue (MB) is an emblematic example of toxic cationic dye, chemically named tetramethylthionine chloride with the chemical formula of  $C_{16}H_{18}N_3S$ . It is extensively used in a variety of industrial processes such as cosmetics, hygienic, textiles, paper coatings, and pesticide industries [10]. A large intake of toxic MB ( $> 7.0$  mg/kg) may result in severe threats including headache, abdominal pain, high blood pressure (hypertension), gastritis, jaundice, respiratory distress, painful micturition, mental disorder, nausea, vomiting, and methemoglobinemia-like syndromes [11].

Many techniques have been developed for the treatment of dye-bearing effluents including ion exchange [12], chemical precipitation [13], coagulation/ flocculation [14,15], ozonation [16], membrane filtration [17], solvent extraction [18], and photocatalytic degradation [19]. The implementation of these sophisticated strategies frequently faces important drawbacks and constraints such as high operational cost, inefficiency for low pollutant concentrations, toxic intermediates products, reagents consumption, or sewage sludge formation. Biosorption constitutes a promising alternative technique for wastewater treatment because of its environmental friendliness and versatility [20, 21]. Indeed, this bioprocess is characterized by remarkable merits, including availability, biodegradability, cost-effectiveness, efficiency, flexibility, simplicity, and reusability. In the case of MB, recent literature highlighted the many possibilities offered by biosorbent-based sorbents or inorganic nanomaterial systems such as alginate/clinoptilolite composite [22], bentonite-ZnO-CuO nanocomposite [23], ball-milled biochar [24], fungal biomass [25], iron nanoparticles [26], pectin-based hydrogels [27].

Chitosan (CS) (constituted of 2-acetamido-2-deoxy- $\beta$ -D-glucopyranose and 2-amino-2-deoxy- $\beta$ -D-glucopyranose residues) is produced by the deacetylation of chitin, naturally occurring in the exoskeletons of crustaceans (i.e. crayfish, crab, cuttlefish, shrimp shells, squids and oyster), fungal cell wall, and insect cuticles [28]. Chitosan-based sorbents are regarded as a cornerstone in various wastewater treatments because of their well-known strong affinity towards different water pollutants (i.e. organic dyes, heavy metals, and pharmaceuticals) thanks to the remarkable abundance of amine ( $-NH_2$ ) and hydroxyl ( $-OH$ ) groups on its structural backbone [29,30]. However, major drawbacks are still associated with the usage of CS-based materials, including low surface area, chemical instability (dissociation) in an acidic environment, colloids formation in water, poor mechanical property, and possible degradation by chemical and/or microbial actions. Interestingly, structural improvement of CS (by crosslinking and/or intercalation with other materials to fabricate bio-composites whether by grafting, blending, and incorporation of CS with other materials) can economically offer the opportunity to overcome these operational limitations [31]. Numerous cross-linkers agents may be used for reinforcing the stability of chitosan, such as epichlorohydrin, glutaraldehyde, ethylene glycol diglycidyl ether, sulfuric acid, and sodium tripolyphosphate. The decline in the reactivity of cross-linked CS, resulting from consumption of available binding ( $-NH_2$ ) groups during the cross-linking process can be compensated by the introduction of new binding sites [32,33].

2-Mercaptobenzimidazole (2-MBI), with the chemical formula of

$C_7H_6N_2S$  (Molecular weight of 150.2 g/mol), is a heterocyclic organic compound containing two electron donor atoms: nitrogen (N) and sulfur (S). This compound has been extensively utilized in a diversity of biological and pharmaceutical activities such as anti-bacterial, anti-cancer, enzyme inhibition, anti-inflammatory, anti-microbial and anti-ulcer activities [34]. Furthermore, it is widely used in non-biological approaches such as anti-oxidant for rubber and plastics, corrosion inhibitors, chelating collectors of some low-grade sulfide minerals [35], and analytical reagents for the determination of various transition metal ions such as Hg(II), Fe(II) and Cd(II). Although, 2-MBI was mainly used for developing corrosion inhibitors, this functionalizing agent (or its analog, 2-MTI, 2-mercaptobenzothiazole) was also used for enhancing the sorption properties of synthetic and bio-based supports [36]. For example, 2-MTI was immobilized on cellulose [37] and synthetic resin for palladium uptake [38]. For rubidium recovery, Guerra et al. [39] used organoclays for the immobilization of MBI. Recently, Mesa et al. [40] reported the immobilization of 2-MBI onto ion-imprinted acrylic acid-based polymer and the removal of methylmercury.

Different techniques were used for immobilizing 2-mercaptobenzimidazole on chitosan-based sorbents, including impregnation mediated by acetone [41], or chemical grafting [42].

The current work investigates the sorption properties of chitosan functionalized with 2-MBI for MB. This is a companion work to another study that focused on the sorption of silver using magnetic (or non-magnetic) chitosan functionalized with 2-MBI [42]. Complementary characterization techniques are used, including for the interpretation of MB binding mechanisms. The second part of the work focuses on the extensive study of sorption properties; including the study of pH effect, sorbent dosage, agitation speed, presence of high salt concentrations; uptake kinetics. The thermodynamics of MB sorption is investigated through sorption isotherms at different temperatures. Dye desorption and sorbent recycling are investigated. In the last part of the work, the impact of solution complexity is evaluated by comparison of sorption properties with spiked solutions of increasing complexity (tap water and seawater).

## 2. Materials and methods

### 2.1. Materials

Chitosan, 2-mercaptobenzimidazole (2-MBI), epichlorohydrin (99%, w/w) were purchased from Sigma-Aldrich (Merck, Darmstadt, Germany). Methylene Blue (MB, 97%) was analytical reagent (AR) grade and supplied by Merck India (Mumbai, India).

### 2.2. Synthesis of sorbent (2-MBI@Chit)

The synthesis of 2-MBI@Chit has been already reported [42] (Scheme S1, see Supplementary information). Briefly, chitosan (5.6 g) and 2-MBI (6.1 g) were dispersed in 250 mL of Milli-Q water under strong agitation (1000 rpm for 30 min in a 500 mL two-necked round-bottomed flask). Epichlorohydrin (4.75 mL) was then added under strong stirring and heating at 70 °C for three hours. After filtration and abundant water rinsing, the solid was dried under vacuum for 6 h at 50 °C. It is noteworthy that the reaction is almost quantitative (17.1 g 2-MBI@Chit for 17.3 g of precursors).

### 2.3. Characterization of materials

The characteristics (and the methods whereof) of 2-MBI@Chit have already been documented [42]. Additional characterization was performed for the interpretation of the interactions of 2-MBI@Chit with MB. The FTIR spectra were collected on a Nicolet IS10 FTIR (Thermo Fischer Scientific, Waltham, MA, USA), equipped with an attenuated total reflectance tool. SEM microphotographs were acquired on a scanning electron microscope (Jeol Ltd.; JSM-6510LV, Tokyo, Japan).

## 2.4. Sorption tests

### 2.4.1. Batch tests

The study of MB sorption was performed in a batch system. For all sorption studies, the process was comprehensively run by varying one of the affecting operational parameters, while keeping the other environmental conditions fixed. The standard conditions corresponded to initial dye concentration of 100 mg MB L<sup>-1</sup> (i.e., C<sub>0</sub>: 0.313 mmol MB L<sup>-1</sup>), pH of 9.3, sorbent dosage (SD) of 1.5 g L<sup>-1</sup>, contact time (time) of 90 min, agitation speed (v) of 200 rpm (Rota bit, J.P. Selecta, Abrera, Spain), and room temperature (i.e., 25 ± 1 °C). Specific experimental conditions are systematically reported in the caption of the figures (see below). After withdrawing and centrifuging the samples, they were analyzed by spectrophotometry at λ<sub>max</sub>: 664 nm [43], using a Palintest 7100 spectrophotometer (Palintest, Ltd., Gateshead, UK). The sorption capacity (q, mmol g<sup>-1</sup>) was deduced from the mass balance equation:

$$q = \frac{(C_0 - C_{eq})}{SD} \quad (1)$$

where C<sub>eq</sub> is the residual dye concentration (mmol L<sup>-1</sup>).

For the study of the pH effect, the initial pH values (pH<sub>0</sub>) were varied between 1.9 and 10.5. The pH was not controlled during the sorption, but the equilibrium pH values were recorded (pH<sub>eq</sub>), using an Aqualytic AL15 pH-meter (Aqualytic GmbH & Co, Dortmund, Germany). For investigating the impact of sorbent dosage, the SD was varied between 0.5 and 5 g L<sup>-1</sup>. The analysis of agitation speed was carried out varying the agitation from 50 to 300 rpm. For the sorption isotherms, the initial dye concentration was varied between 0.0313 and 3.13 mmol MB L<sup>-1</sup>. Sorption isotherms were performed at temperatures ranging between 25 °C and 55 °C (samples being agitated in a shaking incubator LSI-3016R, LabTech S.r.l., Sorisole (BG), Italy). For the evaluation of interfering ions (herein NaCl), the same experimental procedure was used, complementing the solution with increasing amounts of salt (corresponding to concentrations in the range: 0.085 mol L<sup>-1</sup> to 0.77 mol L<sup>-1</sup>).

For uptake kinetics, 1 L of dye solution was mixed with 1.5 g of 2-MBI@Chit for 180 min, samples were collected affixed contact times, filtrated and analyzed for residual concentrations, and the concentration of the dye in the sorbent was calculated by the decrement method:

$$q(t) = \sum_{i=1}^n \frac{(C(t)_{(i-1)} - C(t)_{(i)}) \times V(t)_{(i-1)}}{m} \quad (2)$$

where C(t)<sub>(i)</sub> (mmol MB L<sup>-1</sup>) is the MB concentration of the withdrawn sample number i at time t and C(t)<sub>(0)</sub> = C<sub>0</sub>, V(t)<sub>(i)</sub> (mL) is the volume of the solution in the flask at sample number i and time t, and m is the mass of the sorbent in the flask. Here, V(t)<sub>(i)</sub> - V(t)<sub>(i-1)</sub> equals 5 mL (the sample volume).

The same batch process was used for the investigation of dye desorption and sorbent recycling. The MB-loaded 2MBI@Chit sorbents (recovered from sorption tests) were first washed for removing absorbed dye. In a second step, the sorbent was mixed with 0.5 M HCl solution (SD: 3 g L<sup>-1</sup>) for 140 min. The suspension was centrifuged; the supernatant was analyzed for residual MB concentration. The collected sorbent was repeatedly rinsed with distilled water until the pH of rinsing water reached 7. The regenerated sorbent was dried for 2 h at 40 °C in an oven (Gallenkamp BS Model OV-160, Loughborough (LE), UK) and subjected for 5 consecutive sorption-desorption cycles. The desorption efficiency (DE, %) was determined by:

$$DE \text{ (\%)} = \frac{\text{Amount of desorbed MB (mmol) into the eluate solution}}{\text{Amount of sorbed MB (mmol)}} \times 100 \quad (3)$$

Final tests were performed on MB-spiked real effluents

(concentration of MB was varied between 0.03 and 0.12 mmol MB L<sup>-1</sup>), using either tap water (collected from Water Supply facilities at Port-Said, Egypt) or seawater collected in the Red Sea coast (Jeddah, Saudi Arabia) to evaluate the impact of the complexity of the solution (background ions) on MB sorption.

All sorption tests were performed in triplicate, and the averages were recorded. The limit of experimental errors on triplicates was systematically below 5%.

The modeling of uptake kinetics and sorption isotherms are performed using a series of conventional models summarized in Tables 1 and 2. The parameters were determined by non-linear regression analysis using the facilities offered by Mathematica® (Wolfram Research, Champaign (IL), USA). The comparison of models was based on the determination coefficients (i.e., R<sup>2</sup>) and the Akaike Information Criterion (AIC, see Table 1).

### 2.4.2. Fixed-bed column tests

The dynamic sorption tests were performed in fixed-bed systems using plastic columns (diameter: 1 cm; height: 10 cm). A small piece of glass wool was placed at the bottom of the column and a known quantity of the sorbent was placed in the column to yield the desired bed height (m: 1 g, BV: 1.92 cm<sup>3</sup>, H: 2.45 cm; m: 2 g; BV: 3.84 cm<sup>3</sup>, H: 4.89 cm; m: 3 g; BV: 5.76 cm<sup>3</sup>, H: 7.34 cm). The MB solution (0.625 mM) was pumped downward through the column at the desired flow rate (2, 4, or 6 mL min<sup>-1</sup>). Samples were collected from the outlet of the column at different time intervals and analyzed for residual dye concentration. The operation of the column was stopped when the outlet metal ion

**Table 1**  
Uptake kinetics – model parameters.

Model	Parameter	Value
Experimental value	q <sub>eq,exp.</sub> (mmol g <sup>-1</sup> )	0.1933
PFORE	Equation [86]	$q(t) = q_{eq,1}(1 - e^{-k_1 t})$
	q <sub>eq,1</sub> (mmol g <sup>-1</sup> )	0.1936
	k <sub>1</sub> × 10 <sup>2</sup> (min <sup>-1</sup> )	4.14
	R <sup>2</sup>	0.996
	AIC	-165
PSORE	Equation [86]	$q(t) = \frac{q_{eq,2}^2 k_2 t}{1 + k_2 q_{eq,2} t}$
	q <sub>eq,2</sub> (mmol g <sup>-1</sup> )	0.2225
	k <sub>2</sub> × 10 (g mmol <sup>-1</sup> min <sup>-1</sup> )	2.38
	R <sup>2</sup>	0.991
	AIC	-148
RIDE	Equation [59]	$\frac{q(t)}{q_{eq}} = 1 - \sum_{n=1}^{\infty} \frac{6\alpha(\alpha+1)\exp\left[\frac{-D_e q_n^2 t}{r^2}\right]}{9 + 9\alpha + q_n^2 \alpha^2}$ With q <sub>n</sub> being the non-zero roots of $\tan q_n = \frac{3q_n}{3 + \alpha q_n^2}$ and $\frac{m q}{V C_0} = \frac{1}{1 + \alpha}$
	D <sub>e</sub> × 10 <sup>11</sup> (m <sup>2</sup> min <sup>-1</sup> )	7.62
	R <sup>2</sup>	0.983
	AIC	-123

q<sub>t</sub> (mmol g<sup>-1</sup>): amount of dye sorbed at time (t); q<sub>eq</sub> (mmol g<sup>-1</sup>): sorption capacity at equilibrium; k<sub>1</sub> (min<sup>-1</sup>): apparent PFORE rate constant; k<sub>2</sub> (g mmol<sup>-1</sup> min<sup>-1</sup>): apparent PSORE rate constant; D<sub>e</sub> (m<sup>2</sup> min<sup>-1</sup>): Effective diffusivity coefficient; r (m): Radius of sorbent particle. The comparison of models was performed using the Akaike Information Criterion, AIC [87]:

$$AIC = N \ln \left( \frac{\sum_{i=0}^N (Y_{i,exp.} - Y_{i,model})^2}{N} \right) + 2N_p + \frac{2N_p(N_p + 1)}{N - N_p - 1}$$

where N is the number of experimental points, N<sub>p</sub> the number of model parameters, Y<sub>i,exp.</sub> and Y<sub>i,model</sub> the experimental and calculated values of the tested variable.

$C_e$  (mmol L<sup>-1</sup>): equilibrium concentration of dye in solution;  $q_{eq}$  (mmol g<sup>-1</sup>): dyes sorption capacity at equilibrium;  $q_{m,L}$  (mmol g<sup>-1</sup>): maximum sorption capacity at saturation of the monolayer (Langmuir);  $b_L$  (L mmol<sup>-1</sup>): Langmuir constant related to dye affinity for reactive groups;  $k_F$  (mmol g<sup>-1</sup>) (L mmol<sup>-1</sup>)<sup>1/n<sub>F</sub></sup>: Freundlich constant relative sorption capacity;  $n_F$ : Freundlich constant related to the sorption capacity and intensity;  $q_{m,S}$  (mmol g<sup>-1</sup>): maximum sorption capacity at saturation of the sorbent (Sips);  $b_S$  (L mmol<sup>-1</sup>): Sips constant related to dye affinity for reactive groups;  $n_S$ : Sips exponent related to the sorption capacity and intensity.

concentration reached its initial concentration.

The Yoon and Nelson model was used for simulating the breakthrough curves (C(t)/C<sub>0</sub>) vs. time or BV (bed volume: Volume passed through the column/volume of fixed bed) [44]:

$$\ln\left(\frac{C(t)}{C_0 - C(t)}\right) = k_{YN}(t - \tau), \quad (4)$$

where  $k_{YN}$  is the Yoon & Nelson rate coefficient (min<sup>-1</sup>),  $t$  is the service time (min) and  $\tau$  (min) corresponds to the required time for reaching the 50% sorbate breakthrough.

The breakthrough curves were also analyzed using the bed-depth service time model (BDST, [45]) derived from the Adams–Bohart model [46]:

$$\ln\left(\frac{C_0}{C_s} - 1\right) = \ln\left[e^{k_{BDST} N_0 H/u} - 1\right] - k_{BDST} C_0 t_s, \quad (5a)$$

where  $u$  is the linear volumetric flow rate (m h<sup>-1</sup>);  $t$  is the service time at breakthrough (herein defined as  $C_b = 0.01 C_0$ , h);  $H$  the height of the column (m);  $C_s$  is the exhaustion concentration (concentration at the outlet of the column corresponding to 0.95 C<sub>0</sub>, mmol L<sup>-1</sup>);  $k_{BDST}$  is the BDST rate (m<sup>3</sup> mol<sup>-1</sup> h<sup>-1</sup>), and  $N_0$  is the bed capacity (mmol L<sup>-1</sup>). Since the exponential term is usually much larger than unit, the Eq. (5a) can be reduced to:

$$t_s = \frac{N_0}{C_0 u} H - \frac{1}{k_{BDST} C_0} \ln\left(\frac{C_0}{C_s} - 1\right) \quad (5b)$$

The critical bed height ( $H_0$ , m) is deduced from Eq. (5b) setting the  $t_s$  value to 0:

$$H_0 = \frac{u}{k_{BDST} N_0 C_0} \ln\left(\frac{C_0}{C_s} - 1\right) \quad (5c)$$

### 3. Results and discussion

#### 3.1. Characterization of sorbent

##### 3.1.1. Reminder on the main characteristics of 2-MBI@Chit

Previous studies have reported the textural properties of 2-MBI-Chit [42]. The specific surface area of the sorbent was 8.1 m<sup>2</sup> g<sup>-1</sup> (deduced from N<sub>2</sub> sorption and desorption isotherm using BET measurements), while the pore size and volume were 24.5 nm and 0.033 cm<sup>3</sup> g<sup>-1</sup>, respectively. The average particle size was determined by DLS measurements close to 486 μm. The zetametric measurements showed that the pH<sub>PZC</sub> is close to 8.3: the sorbent is protonated in acid media. The CHNS analysis (elemental analysis) revealed that sulfur content reaches 2.95 mmol S g<sup>-1</sup> while the nitrogen content was 7.36 mmol N g<sup>-1</sup>. Elwakeel et al. [42] commented that the theoretical N/S molar ratio (i. e., 2.49) is lower than expected (i.e., 3:1), based on the structure of 2-MBI (2 N per S) and the immobilization of a molecule of 2-MBI per amine group on chitosan (for full substitution). This means that all the amine groups are not grafted by 2-MBI, probably because the proposed structure (which suggests interlinkage between 2 molecules of 2-MBI through epichlorohydrin) is not fully operative on each amine groups of chitosan (grafting only one MBI instead of two MBI groups).

Thermogravimetric analysis showed four phases in the thermal degradation of the sorbent: (a) water release (~ 6.7% up to 130–140 °C), (b) steep and important weight loss (~ 30%, up to 280–290 °C), associated with the degradation of substituents on chitosan backbone, (c) progressive weight loss till 440 °C (degradation of chitosan backbone and char formation), and (d) decomposition of the char.

##### 3.1.2. SEM observations

Fig. S1 compares the surface morphology of sorbent particles before and after MB sorption. Apparently, the surface appears to be smoothed after dye sorption. The sorbent (2-MBI@Chit) initially shows some irregular structures that bring porosity and greater surface area for exchange (right side of relevant micrograph). These irregularities are substantially decreased after dye uptake, with brighter micro-objects at the surface.

##### 3.1.3. FTIR characterization of the interactions between 2-MBI@Chit and MB

Fig. S2 shows the FTIR spectra of 2-MBI@Chit before and after dye sorption. The global shape of the spectra does not change after dye uptake. Table S1 reports the main peaks and their assignments. The broad and intense band centered around 3440 cm<sup>-1</sup> is assigned to the combined contributions of –OH and –NH groups. In the region 1200–900 cm<sup>-1</sup>, the broad band with several peaks represents the fingerprint of the carbohydrate ring of chitosan [47]. The absence of relevant peaks at 962 cm<sup>-1</sup> and 925 cm<sup>-1</sup>, which are representative of the C–C bonds of epoxide functions from epichlorohydrin [47], means that the epoxide ring was completely opened for grafting 2-MBI. This is consistent with the relatively high yield of the synthesis (> 98%). The FTIR spectrum of MB show abundant sharp peaks in the range 1700–800 cm<sup>-1</sup> [48], which are superposed to the “peak forest” associated to 2-MBI/epichlorohydrin/chitosan system. It is thus difficult identifying precise changes; the most significant changes are associated with the decrease in the relative intensity of some peaks (Fig. 1 – spectra focused on 2000–400 cm<sup>-1</sup>). For example, the broad band centered at 1682 cm<sup>-1</sup> is widened (with the intensification of the shoulder around ~ 1645 cm<sup>-1</sup>). The relative intensity of the peak at ~ 1565 cm<sup>-1</sup> is reduced: N–H functional groups are probably involved in dye binding. The relative intensities of the peaks at 1439 cm<sup>-1</sup> (shoulder converted into a more marked peak), 1416 cm<sup>-1</sup> (shifted to 1411 cm<sup>-1</sup>), and 1375 cm<sup>-1</sup> (shifted to 1379 cm<sup>-1</sup>) are also decreased (in addition to shifts). These changes demonstrate that the environment of N–C=S and C–O reactive groups are affected by the sorption of the dye and that their

Fig. 1. FTIR spectra of 2-MBI@Chit before and after MB sorption (focus on the wavenumber range: 2000–400  $\text{cm}^{-1}$ ).

respective reactive groups are involved in dye uptake. The interpretation of the sorption mechanism is made complex by the diversity of reactive groups but also the specific properties of the dye. Indeed, MB can readily appear under different resonance forms depending on the pH, the temperature, and the redox conditions: the cationic charge may be localized on either the heterocyclic sulfur site or the exocyclic nitrogen atom [49]. In the case of MB sorption onto chitosan-epichlorohydrin immobilized on zeolite, the spectra of the sorbent before and after MB sorption were also weakly changed: the most significant differences were also reported close to  $1450 \text{ cm}^{-1}$  and around  $1659 \text{ cm}^{-1}$  [50].

### 3.2. Investigation of sorption properties

#### 3.2.1. Effect of pH

The pH is a critical parameter in the design and optimization of sorption processes because of its dual effect on both the charge of the sorbent (protonation/deprotonation of reactive groups) and the speciation of the solute (pH vs.  $\text{pH}_{\text{PZC}}$ ). The  $\text{pH}_{\text{PZC}}$  of 2-MBI@Chit was found close to 8.3 [42], while the  $\text{pK}_a$  of MB is reported close to 3.8 [51]. Fig. 2 shows the progressive and linear increase of the sorption of MB with the increase of the pH of the solution; the sorption efficiency (not shown) allows the quasi complete recovery of the dye at  $\text{pH} \sim 10$  (sorption efficiency,  $\text{SE} > 92\%$ ), under selected experimental conditions. At pH below 8.3, the sorbent is protonated. On the other hand, the dye remains

Fig. 2. Effect of pH on MB sorption using 2-MBI functionalized chitosan (2-MBI@Chit) – sorption capacity, pH variation and distribution ratio ( $\log_{10}$ -plot, insert) ( $C_0$ :  $100 \text{ mg MB L}^{-1} = 0.313 \text{ mmol MB L}^{-1}$ ; Sorbent dosage, SD:  $1.5 \text{ g L}^{-1}$ ; T:  $25 \pm 1 \text{ }^\circ\text{C}$ ; Time: 90 min; Agitation speed,  $v=200 \text{ rpm}$ ).

cationic at pH below 3.8; meaning that the repulsion effect strongly limits the sorption efficiency in acidic solutions, while the repulsion decreases with increasing the pH above pH 4. However, MB sorption at acidic pH values is non-negligible: for example at  $\text{pH}_0$  1.6 and  $\text{pH}_{\text{eq}}$  3.3, the sorption capacity reaches  $0.115 \text{ mmol MB g}^{-1}$  vs.  $0.194 \text{ mmol MB g}^{-1}$  at  $\text{pH}_0$  11 –  $\text{pH}_{\text{eq}}$  10.2. This relatively high sorption capacity under unfavorable conditions regarding ionic charges probably means that other mechanisms are involved in the binding of MB on the sorbent. Gayathri and Palanisamy [52] investigated MB sorption on glucose-/glucosamine grafted polyacrylamide graphite composite. They reported a series of different potential mechanisms for the binding of MB, including:

- H-bonding (between dye ring and  $-\text{OH}$  groups of the sorbent),
- electrostatic interaction (between protonated sulfur on MB and N atoms on the sorbent),
- dipole-dipole H-bonding (between  $> \text{N}^{\delta-}$  on MB and  $-\text{OH}^{\delta+}$  on the carbohydrate unit), and
- $n-\pi$  interaction (between the dye ring and the O in OH group or amine groups of the sorbent).

As the pH increases the protonation of the sorbent decreases, which, in turn, reduces the repulsion effect for the binding of the dye. Sousa et al. [51] investigated the sorption of MB on mineral sorbents (plasma activated palygorskites) and they reported the distribution of protonated MB species. Different levels of protonation are identified in the range pH 0–6. Below pH 1, MB bears 3 cationic charges on N (2 lateral groups and thiazole ring). In the range pH 1–2, trivalent cation co-exists with two divalent cations (2 lateral N and thiazole/lateral N group). Between pH 2 and 3, the predominant species is the divalent species (2 lateral N groups) with the appearance of increasing amounts of monovalent cationic species (one lateral N group protonated). Above pH 4, the monovalent cationic species is the unique species present in the solution. The complexity of the system is even increased by the contribution of mesomeric effects (with charge displacement from N in thiazole to S). The increase in sorption capacity is then the double effect of deprotonation of the sorbent and decrease in the number of cationic charges hold by the dye.

Fig. 2 also shows the pH variation during the sorption of MB. Below the  $\text{pH}_{\text{PZC}}$  value, the final pH is increased compared with the initial pH value, especially for  $\text{pH}_0$  below 5.1 ( $\text{pH}_{\text{eq}}$  5.5): by up to 1.4–1.5 pH unit in the most acidic solutions. Above  $\text{pH}_{\text{PZC}}$ , the final pH is a little higher than the initial pH (by less 0.7 pH unit). At pH above  $\text{pH}_{\text{PZC}}$  (i.e., 8.3) the deprotonation of the sorbent makes easier the sorption of the cationic dye: the highest sorption capacities are obtained at pH close to 10.

The insert in Fig. 2 shows the  $\log_{10}$  plot of the distribution ratio ( $D = q_{\text{eq}}/C_{\text{eq}}$ ) vs. the equilibrium pH. The data are aligned according to a linear trend with a slope close to +0.15. In pure ion-exchange mechanisms, this slope is usually correlated to the number of protons exchanged with the solution during its sorption and serves to evaluate the stoichiometric ratio between the reactive groups and the bound solute. Here, the stoichiometric ratio is not coherent with charge stoichiometry. This is another evidence that the binding mechanism is relatively complex and involves different modes of interactions. In the case of MB sorption onto fava bean peel waste, Bayomie et al. [53] also reported that MB sorption involves both electrostatic and non-electrostatic mechanisms. Scheme 1 shows the tentative mechanisms involved in MB sorption onto 2-MBI@Chit. Further sorption tests have been performed at pH 9.3.

#### 3.2.2. Effect of sorbent dosage

Increasing the sorbent dosage improves the recovery of the dye (Fig. 3). However, the beneficial effect of high sorbent dosages is relatively limited: the sorption efficiency only increases from 90.6% to 95.9% when the SD increases from 0.5 to  $5 \text{ g L}^{-1}$ . Therefore, the sorption capacity drastically decreases because of the relatively poor use of

**Scheme 1.** Suggested mechanisms of MB sorption on 2-MBI@Chit.

**Fig. 3.** Effect of sorbent dosage on MB sorption using 2-MBI@Chit – sorption capacity and sorption efficiency ( $C_0$ : 100 mg MB L<sup>-1</sup> = 0.313 mmol MB L<sup>-1</sup>; pH 9.3; Sorbent dosage, SD: 0.5–5 g L<sup>-1</sup>; T: 25 ± 1 °C; Time: 90 min; Agitation speed, v-200 rpm).

the excess of sorbent compared with dye concentration. Under selected experimental conditions, the sorption capacity drops from 0.567 to 0.06 mmol MB g<sup>-1</sup>. For further experiments the sorbent dosage was set to 1.5 g L<sup>-1</sup>; this sounds to be a good compromise between solution exhaustion (removal of the dye) and the saturation of the sorbent.

### 3.2.3. Effect of ionic strength (NaCl concentration)

The sorption performance may be strongly affected by the complexity of the solution. It is thus important to design systems where the sorbent is highly selective for target solute [54]. For instance, in the textile industry dyes may be fixed up using adjuvants such as salts. For this reason, in order to approach the real typology of effluents, the effect of increasing concentrations of NaCl on the sorption of MB was investigated. Fig. 4 shows that the presence of salt decreases the sorption efficiency of 2-MBI@Chit for MB binding. Sodium cation may compete with MB for binding onto 2-MBI@Chit. Other mechanisms may be involved in the inhibition of dye sorption including (a) a screening/shield effect (with a simultaneous decrease in the electrostatic interaction between the surface and the sorbate), and (b) the increase in

**Fig. 4.** Effect of the addition of NaCl on MB sorption using 2-MBI@Chit – sorption capacity and sorption efficiency ( $C_0$ : 100 mg MB L<sup>-1</sup> = 0.313 mmol MB L<sup>-1</sup>; pH 9.3; Sorbent dosage, SD: 1.5 g L<sup>-1</sup>; T: 25 ± 1 °C; Time: 90 min; Agitation speed, v-200 rpm).

the ionic strength that affects the activity of the dye in the solution [17]. However, even with such a huge excess of NaCl as 45 g L<sup>-1</sup> (i.e., 0.77 mmol L<sup>-1</sup>) the sorption efficiency only decreases from 92.4% to 69.0%. The sorption capacity decreases by 25% (from 0.192 to 0.144 mmol MB g<sup>-1</sup>). This means that the sorption system is resilient despite the complexity of the solution. Similar conclusions were commented by Chen et al. [55] for MB sorption onto Fe<sup>3+</sup>-stabilized magnetic polydopamine composite. In the case of sponge/graphene oxide composite, Nayl et al. [56] reported much higher impact of salinity on MB sorption: sorption efficiency decreases from ~ 92% to ~ 54% with the addition of NaCl at the concentration of 10 g L<sup>-1</sup> (under selected experimental conditions). The insert in Fig. 4 shows the log<sub>10</sub> plot of the distribution ratio vs. the concentration of NaCl; in the presence of NaCl the plots are roughly linear with a slope of -0.83. The stoichiometric ratio approaches 1; meaning that each dye molecule released is probably exchanged with one Na<sup>+</sup> ion. The sorbent is very robust in terms of MB sorption in complex solutions; this is a promising property in the perspective of the industrial transfer.

### 3.2.4. Uptake kinetics and mass transfer analysis

The sorption process may be controlled by different mechanisms of heat transfer, mass transfer, and chemical reaction rates. The contributions of resistance to mass transfer have been abundantly documented, including resistances to bulk diffusion, film diffusion, and intraparticle diffusion. A proper agitation mode allows neglecting the resistance to bulk diffusion. On the other side, one of the most important factors affecting the resistance to film diffusion is the agitation speed. The next section compares the kinetic profiles for different agitation speeds. After optimization of this critical experimental parameter, the kinetic profiles are modeled using the Crank equation (resistance to intraparticle diffusion, RIDE) and the conventional chemical reaction rates of first and second-order (these models initially developed for homogeneous chemical reaction have been extended to describe heterogeneous systems): pseudo-first order rate equation (PFORE) and pseudo-second order rate equation (PSORE). The relevant equations are summarized in Table 1.

**3.2.4.1. Effect of agitation speed.** The sorption capacity of 2-MBI@Chit for MB is compared (after 90 min of contact) for different speeds of agitation (in the range 50–300 rpm) (Fig. S3). The contact time set at 90 min may be insufficient in some cases for reaching the equilibrium. However, this experimental procedure is sufficient for measuring the effect of agitation speed on sorption performance. Increasing the agitation speed linearly increases both the sorption efficiency and

sorption capacity in the range 50–200 rpm. When the agitation speed reaches 200 rpm, the sorption performance tends to stabilize; increasing the agitation speed above this limit value is not justified. This agitation speed was selected for sorption tests.

**3.2.4.2. Modeling of uptake kinetics.** Fig. 5 shows the kinetic profile for the sorption of MB using 2-MBI@Chit under optimized conditions. The equilibrium is reached within 90 min of contact. Fig. 5 also compares the modeling of experimental data using the PFORE, the PSORE, and the RIDE. Table 1 reports the parameters of these different models. Consistently with Fig. 5, the PFORE fits better experimental profile than the PSORE and the RIDE (as shown by both  $R^2$  and AIC values). The higher quality of the PFORE fit is also clearly demonstrated by the calculated values of the sorption capacity at equilibrium (i.e., 0.1936 mmol MB  $g^{-1}$ ), which is much closer to the experimental value (i.e., 0.1933 mmol MB  $g^{-1}$ ) than in the case of PSORE (i.e., 0.2225 mmol MB  $g^{-1}$ ) (Table 1). The apparent rate coefficient,  $k_1$ , is close to 0.041  $min^{-1}$ .

The modeling of experimental kinetic profiles is abundantly focused in the literature on PFORE and PSORE models because of the simplicity of the computer facilities required for the determination of apparent constants and the relatively good fit of profiles. However, several contributions recently pointed out the inappropriate use of these simple equations [57,58] for modeling sorption kinetics. Among the possible parameters that introduce bias in the interpretation are the excess of sorbent compared with solute concentration (which drastically changes the residual concentration of the solute that should be kept roughly constant) [58], or sorption capacity too close from the saturation [57], among other possible mistakes in the methodology and design of kinetic studies. More specifically, these studies are concluding that frequently the best fit of experimental data by the PSORE is hiding the control of uptake kinetics by resistance to intraparticle diffusion. Therefore, the direct interpretation of PFORE and PSORE as physically- or chemically-driven mechanisms, respectively, must be considered very cautiously. This may be considered a simple tool for comparing profiles rather than direct interpretation of mechanisms, especially in the case of inappropriate design of experimental conditions.

The RIDE (so-called Crank equation [59]) allows approaching the effective intraparticle diffusion constant ( $D_e$ ), which is found close to  $7.6 \times 10^{-11} m^2 min^{-1}$ . This is three orders of magnitude lower than the values reported for MB diffusivity in water (i.e.,  $4.04 \times 10^{-11} m^2 min^{-1}$  [60]). This means that the resistance to intraparticle diffusion plays a significant role in the overall control of uptake kinetics.

Alternative modeling can bring complementary insight on the sorption/desorption rates process (such as the Elovich equation, [61,62]) or

the contribution of the diffusion modes (Weber and Morris equation, [63]) (Fig. S4). Fig. S4a shows that the Elovich equation fits well the initial section of the uptake kinetics (first minutes of contact) but fails to describe the second part of the curve. The plot of the sorption capacity (i.e.,  $q(t)$ ) vs. the square root of time allows identifying three sections corresponding to:

- the first minutes (usually controlled by the resistance to film diffusion),
- the intermediary range, where most of the sorption takes place, which is controlled by resistance to intraparticle diffusion, and
- the final section covering the saturation of the sorbent (with a progressive filling of the internal microporous sites).

When the linear plot of sorption capacity against the square root of time does not pass through the origin, it is generally accepted that the resistance to film diffusion is playing a role in the control of mass transfer [64]; this is especially the case within the first minutes of contact. These results confirm the contribution of resistance to intraparticle diffusion in the control of kinetic profiles for the sorption of MB onto 2-MBI@Chit. The PFORE allows the best mathematical fit of experimental data. It is noteworthy that this fast kinetic performance is improved by sonochemical treatments [42,65].

### 3.2.5. Sorption isotherms and thermodynamic parameters

With increasing the concentration of the dye, it is possible progressively approaching the saturation of the sorbent and establishing the sorption isotherms (Fig. 6). The maximum sorption capacity is close to 1.28 mmol MB  $g^{-1}$  at room temperature (i.e.,  $25 \pm 1^\circ C$ ). The sum of N and S reactive groups is close to 10.3 mmol  $g^{-1}$ . The molar ratio MB/(N + S) is close to 0.125; this is lower (but of the same order of magnitude) than the calculated stoichiometric ratio (i.e., 0.15) from the slope of the curve  $\log_{10} D$  vs. pH. A steep initial slope, followed by the formation of a saturation plateau, characterizes the shape of the sorption isotherms (carried out at different temperatures, in the range 25–55  $^\circ C$ ). Both the initial slope and the values of the saturation plateaus (sorption capacity at saturation) slightly increase with the temperature. The sorption of MB onto 2-MBI@Chit is endothermic; this is consistent with the results reported by Al-Ghouti and Al-Absi [66] for the sorption of MB onto olive stones. The modeling of sorption isotherms was processed using conventional equations reported in Table 2.

The shape of the curves is characteristic of systems described by the Langmuir equation; the Freundlich equation is a power-like function (exponential trend), which is not consistent with the saturation plateau.

Fig. 5. Uptake kinetics – comparison of fitting model ( $C_0$ : 100 mg MB  $L^{-1}$  = 0.313 mmol MB  $L^{-1}$ ; pH: 9.3; Sorbent dosage, SD: 1.5  $g L^{-1}$ ; T:  $25 \pm 1^\circ C$ ; Agitation speed,  $v$ -200 rpm).

Fig. 6. Effect of temperature on MB sorption isotherms using 2-MBI@Chit – Langmuir equation fitting ( $C_0$ : 10–1000 mg MB  $L^{-1}$  = 0.0313–3.13 mmol MB  $L^{-1}$ ; pH 9.3; Sorbent dosage, SD: 1.5  $g L^{-1}$ ; T: 25–55  $\pm 1^\circ C$ ; Time: 90 min; Agitation speed,  $v$ -50–300 rpm).

The Langmuir equation appears to be more appropriate for fitting experimental results. This is consistent with the results summarized in Table 2. The Langmuir equation supposes the sorption to be homogeneous (in terms of the distribution of sorption energies at the surface of the sorbent), and that sorption occurs as a monolayer without interactions between sorbed molecules. The Sips mathematical equation introduces a supplementary adjustable parameter (being a combination of the Langmuir and the Freundlich equations). This third adjustable parameter allows improving the quality of the fit of experimental profiles; the calculation of the AIC parameter (which takes into account the number of adjustable parameters in the models) confirms that this model is significantly better than the Langmuir equation for describing sorption profiles, except at T: 55 °C. The differences are usually considered significant when the  $|\Delta AIC| > 2$ . In Fig. 6, the experimental data are fitted by the Langmuir equation (solid lines); the Sips modeling is presented in Fig. S5.

Table 2 shows that the Langmuir modeling overestimates the maximum sorption capacity by 17–12% (only 9–6% for the Sips model). The effect of temperature is more significant on the initial slope of the sorption isotherm (correlated with the affinity coefficient of the sorbent for the solute; the initial slope is  $\approx q_{m,L} \times b_L$ ) than on the sorption capacity at saturation (by 3% between 25 °C and 55 °C). The variations of the affinity coefficients, after conversion into dimensionless parameters ( $b_L^*$  and  $b_S^*$ ) [67] can be used for calculating the thermodynamic parameters using the van't Hoff plots:

$$\Delta G^\circ = -RT \ln b_L^* \text{ or } \Delta G^\circ = -RT \ln b_S^* \quad (6a)$$

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \quad (6b)$$

where  $\Delta H^\circ$  ( $\text{kJ mol}^{-1}$ ),  $\Delta G^\circ$  ( $\text{kJ mol}^{-1}$ ), and  $\Delta S^\circ$  ( $\text{J mol}^{-1} \text{K}^{-1}$ ) are the enthalpy change, the free Gibbs energy change, and the entropy change, respectively (with T: the temperature in K, and R: the ideal gas constant). The parameters can be obtained from:

$$\ln b_L^* = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \text{ or } \ln b_S^* = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} \quad (6c)$$

Fig. 7 shows the relevant van't Hoff plots (for both  $b_L$  and  $b_S$ ). The values of the enthalpy change are consistent for the two calculations: 10.84–11.75  $\text{kJ mol}^{-1}$ , while the entropy change is close to 114.3–112.7  $\text{J mol}^{-1} \text{K}^{-1}$ . Table 3 summarizes the thermodynamic parameters. The positive values of enthalpy change confirm the endothermic character of the sorption of MB onto 2-MBI@Chit, while the positive values of the entropy change indicate that the randomness of the system increases. With the absolute value of  $|T\Delta S^\circ|$  being greater than  $|\Delta G^\circ|$ , the sorption mechanism appears to be controlled by entropy

Fig. 7. Analysis of the thermodynamics of MB sorption using 2-MBI@Chit - van't Hoff plots (derived from Figs. 5 and S5, with extraction of affinity coefficients from Langmuir and Sips equations, respectively).

rather than enthalpy. Shahwan recently discussed in deep the significance of negative values of  $\Delta G^\circ$ . Contrary to the conventional interpretation on the spontaneity of the sorption process [69], Shahwan, [68] preferred considering that the sorption is only favored when  $\Delta G^\circ$  is negative. In addition, he pointed out the importance of considering the contribution of the dehydration effects in the discussion of enthalpy and entropy changes [68]. As a complement to previous comments reported by Lima et al., [67] the appropriate conditions for comparing and interpreting the values of thermodynamic parameters require careful attention and moderation in conclusions.

These orders of magnitude (and the specific relevant characters/signs of  $\Delta H^\circ$ ,  $\Delta G^\circ$ , and  $\Delta S^\circ$  values) in the thermodynamics of MB sorption are consistent with the values reported for MB sorption onto  $\text{Fe}^{3+}$ -stabilized magnetic polydopamine composite [55]. For MB sorption onto cellulose olive stones, the same trends were observed though the intrinsic values of enthalpy and entropy changes were significantly higher [66]. The enthalpy changes required for MB sorption onto sugarcane bagasse [70], activated carbon/cellulose films [1], and graphene oxide/alkali lignin aerogel [71] are about one order of magnitude lower than for 2-MBI@Chit. The enthalpy changes for gellan-pullulan nanogels were reported around 5  $\text{kJ mol}^{-1}$  [2]. On the opposite hand, the sorption of MB onto silica-based sorbents [10] and n-layer aminated graphene oxide [72] shows higher values for the entropy change and high negative values for the enthalpy change.

Several studies have shown the possibility for methylene blue to aggregate in acidic solution [73]; though this effect tends to decrease at neutral or alkaline pH [74]. This may strongly influence the sorption performance in terms of both kinetics (increase of the volume and size of the solute, which, in turn, may affect the resistance to intraparticle diffusion) and equilibrium (accessibility to internal reactive groups, steric hindrance, stoichiometric ratio between functional groups on the dye and the reactive groups on the sorbent). Li et al. [75] pointed out the strong importance of the adsorption orientations of the dyes molecules on the binding performance (which may be influenced by the temperature). Walker and Weatherley characterized the contributions of dye aggregation and sorbent porosity (activated carbon and bone char) on dye sorption [76]. Luo et al. [77] reported the occurrence of in situ aggregation of adsorbed MB in the porosity of  $\text{WO}_3$  nanosheets. These different mechanisms of aggregation (both in liquid and at the surface of the sorbent) may obviously affect the thermodynamics of sorption, especially at the level of entropy effect since the randomness of the system decreases with the aggregation and precipitation of the solute. This mechanism was already documented in the case of amphiphilic molecules [78] and the adsorption of dyes onto anionic surfactant-coated mesoporous aminopropyl silica [79].

The sorption properties of 2-MBI@Chit for MB sorption are compared with the binding performances of alternative sorbents recently reported in the literature (Table S2). The experimental conditions are significantly different, especially in terms of selected pH values. Apart from this parameter, the criteria of equilibrium time and Langmuir parameters allow roughly comparing these materials. Some materials show outstanding sorption capacities, such as lignocellulose-poly(acrylic acid)/clay composite (i.e., 6.25  $\text{mmol MB g}^{-1}$ , at pH 5 [80]), graphene oxide/lignin aerogel (i.e., 3.62  $\text{mmol MB g}^{-1}$ , at pH 7 [71]) or acrylic acid-grafted multiwall carbon nanotubes (i.e., 1.91  $\text{mmol MB g}^{-1}$  at pH 7 [81]). With a maximum sorption capacity at saturation of the monolayer close to 1.5  $\text{mmol MB g}^{-1}$ , 2-MBI@Chit is part of the most efficient sorbents recently reported: besides, to high sorption capacity, the equilibrium time (90 min, under selected experimental conditions) is one of the shortest among the best sorbents. The combined kinetic and equilibrium properties of 2-MBI@Chit make this material a promising support for the removal of MB from aqueous solutions.

### 3.2.6. Dye desorption and sorbent recycling

The design of functionalized materials contributes not only to the

**Table 3**

Thermodynamic parameters for MB sorption onto 2-MBI@Chit.

T (K)	Based on Langmuir fit					Based on Sips fit				
	$\Delta H^0$	$\Delta S^0$	$-\Delta G^0$	$T\Delta S^0$	$R^2$	$\Delta H^0$	$\Delta S^0$	$-\Delta G^0$	$T\Delta S^0$	$R^2$
298	11.75	112.7	21.83	33.58	0.993	10.84	114.3	23.23	34.07	0.997
308			22.96	34.71				24.37	35.22	
318			24.08	35.84				25.52	36.36	
328			25.21	36.96				26.66	37.50	

 $\Delta H^0, \Delta G^0, T\Delta S^0$ : kJ mol<sup>-1</sup>;  $\Delta S^0$ : J mol<sup>-1</sup> K<sup>-1</sup>.

improvement of sorption properties but also to the increase in the cost of the sorbent (and of the process of dye recovery). This means that the recycling of the sorbent is a challenge especially important (compared with low-cost sorbents or biosorbents that could justify a simple step processing). This constraint motivated the investigation of dye desorption and sorbent recycling. Since the study of pH effect on MB sorption clearly revealed that the efficiency of dye removal increases with the pH. Therefore, the use of acidic solutions appeared as a potential solution for dye release from loaded-sorbent. Preliminary tests (not shown) demonstrated that 0.8 M HCl solution is highly efficient for dye desorption. Fig. S6 shows the kinetic profile for MB desorption: the fraction of dye released from the sorbent increases almost linearly up to 100 min (contact time) before tending to stabilize. The maximum desorption (at 140 min) reaches up to 94.5%: a fraction of the dye cannot be released under selected experimental conditions (i.e., SD: 3 g L<sup>-1</sup>, while for uptake kinetics the SD was 1.5 g L<sup>-1</sup>). Under these conditions, the sorption is completely reversible but allows concentrating the dye in a smaller volume than for the loading step. Fig. S6 also shows the superposed fits of experimental profiles with both the PFORE and PSORE. The simulated curves roughly follow the experimental trend, despite some inaccuracies are driven by the “wavy-like” shape of the experimental results. It is noteworthy that the PFORE and PSORE fail to fit the final section of the curves: the models suppose the dye to be completely released (contrary to the experimental stabilization of desorption efficiency close to 94.5%). Despite the poor quality of these fits (evidenced by the strong overestimation of the calculated initial dye content), the apparent rate constants may be used to roughly compare uptake and desorption rates. Both the PFORE and PSORE apparent rate coefficients for the desorption step are significantly lower than for the uptake. Taking into account specifically the PFORE (which was significantly better for MB sorption than the PSORE), the apparent rate coefficient is decreased from 0.041 min<sup>-1</sup> to 0.0052 min<sup>-1</sup>. This is notable since, in many cases involving the sorption/desorption of metal ions, desorption is generally faster than sorption; a reciprocal trend is observed herein with MB.

Table 4 evaluates the recycling of the sorbent for five successive sorption/desorption cycles (using 0.8 M HCl solutions as the eluent). The sorption capacity slightly decreases with re-use; however, even after five cycles the loss is less than 5%. The performance stability is even higher in terms of desorption efficiency: the decrease at the fifth cycle is less than 2%; actually, the desorption efficiency stabilizes at 92.4–92.5% after the third cycle (against 94.1% at the first step).

This remarkable stability makes the sorbent very promising for MB recovery (as an example of cationic dyes); although it would be

**Table 4**  
Sorption/desorption cycles.

Step Cycle	Sorption		Desorption
	$q_{eq}$ (mmol MB g <sup>-1</sup> )	Loss (%)	Efficiency (%)
#1	0.1928	–	94.1
#2	0.1917	0.57	93.5
#3	0.1903	1.30	92.4
#4	0.1880	2.49	92.5
#5	0.1836	4.76	92.5

necessary to evaluate this performance with complex effluents (which composition could involve the progressive poisoning of the sorbent with competitor solutes, including molecules poorly desorbable). Similar remarkable stability was also reported for sorbents such as n-layer aminated graphene oxide [72] (for 10 cycles) or Saudi red clay [82].

### 3.2.7. Dynamic sorption of MB – fixed-bed reactor

The breakthrough curves may be controlled by many parameters such as the size of sorbent particles and the flow rate (for their respective effects on resistance to intraparticle diffusion and film diffusion), the column height, the concentration of the dye, the temperature, etc. Fig. 8a shows the effect of increasing the flow rate from 240 mL h<sup>-1</sup> (superficial flow velocity, SFV: 0.306 m h<sup>-1</sup>) to 300 mL h<sup>-1</sup> (SFV: 0.382 m h<sup>-1</sup>) (for a column height of 4.89 cm). The curves show the characteristic sigmoidal shape. Increasing the flow rate decreases the breakthrough time (corresponding to outlet concentration: 1% of C<sub>0</sub>): from 373 min (i.e., 389 BVs) to 204 min (i.e., 319 BVs). On the other side, the exhaustion point (corresponding to C<sub>out</sub> = 0.95 C<sub>0</sub>) increases from 1296 BVs (i.e., 1244 min) to 1925 BVs (i.e., 1232 min) (Table 5). Therefore, the sorption capacity at saturation slightly increases with

**Fig. 8.** Breakthrough curves for MB sorption onto 2-MBI@Chit – effect of flow rate (a) and column height (b) (solid lines: sorption capacity  $q(V)$ ; C<sub>0</sub>: 0.625 mmol MB L<sup>-1</sup>; pH<sub>0</sub>: 9.3).

**Table 5**  
Modeling of breakthrough curves – parameters.

H	Q	$k_{YN} \times 10^3$	$\tau$	$q_{max}$	$t_b$	$t_s$	$k_{B-A}$	$N_0$	$H_0$
4.89	2	4.00	1627	0.972	562	2054			
4.89	6	15.4	666	1.188	204	1232			
2.45	4	14.6	483	1.173	194	688	0.1391	298.9	0.56
4.89	4	7.35	915	1.103	373	1245			
7.34	4	5.20	1292	1.051	653	1680			

H and  $H_0$ : cm; Q:  $\text{mL min}^{-1}$ ;  $k_{YN}$ :  $\text{min}^{-1}$ ;  $\tau$ ,  $t_b$  and  $t_s$ : min;  $q_{max}$ :  $\text{mmol MB g}^{-1}$ ;  $k_{B-A}$ :  $\text{L mmol}^{-1} \text{min}^{-1}$ ;  $N_0$ :  $\text{mmol L}^{-1}$ .

flow rate from  $1.10 \text{ MB g}^{-1}$  to  $1.19 \text{ mmol MB g}^{-1}$ ; these values are consistent with the sorption isotherms: sorption capacity for  $C_{eq}$ :  $0.625 \text{ mmol L}^{-1}$  is close to  $1.28 \text{ mmol MB g}^{-1}$  (calculated by the Langmuir equation), which corresponds to the maximum sorption capacity ( $q_{eq,exp}$ ).

The increase in flow rate is supposed to reduce the contact time inside the column (for fixed column height); however, this drawback is apparently counterbalanced by a forced flux that allows enhancing the contact of the solution with all the sorbent particles (avoiding preferential channeling). However, these differences are poorly marked.

The amount of sorbent was varied to test various column heights (2.45 cm, 4.89 cm, and 7.34 cm) (Fig. 8b) at a flow rate of  $240 \text{ mL h}^{-1}$  (SFV:  $0.306 \text{ m h}^{-1}$ ). The breakthrough hardly varies with the column height: 389 BVs, 404 BVs, and 453 BVs, respectively. Above 700 BVs, the slope of the curve progressively decreases with increasing the column depth: the residence time increases delaying the exhaustion of the column (i.e., 1170 min, 1250 min, and 1438 min). The exhaustion time increases with the bed height because the lifetime of the sorption zone increases with the length of the sorption zone [46]. Therefore, the sorption capacity increases with the depth of the column from  $1.05 \text{ mmol MB g}^{-1}$  up to  $1.17 \text{ mmol g}^{-1}$ .

The Bohart-Adams model was applied considering the evolution of the breakthrough time against the column height (Fig. S7). The capacity of the column is evaluated to  $N_0$ :  $299 \text{ mmol MB L}^{-1}$ ; this is higher than the values reported for MB sorption on cedar sawdust [83]. Based on an apparent volumetric density of  $521 \text{ g L}^{-1}$  (i.e., 1 g occupying  $1.92 \text{ mL}$ ), the sorption capacity stands to  $0.574 \text{ mmol MB g}^{-1}$ . This value is significantly higher than the value deduced from the Langmuir equation for an equilibrium concentration  $C_{eq} = 0.00625 \text{ mmol MB L}^{-1}$  (i.e.,  $0.061 \text{ mmol MB g}^{-1}$ ). This is only a fraction of the sorption capacity available under batch experimentation; similar conclusions were reached in the case of the sorption of reactive yellow with activated carbon [46].

The Bohart-Adams rate coefficient is close to  $0.139 \text{ L mmol}^{-1} \text{min}^{-1}$ . These values are of the same order of magnitude as the values reported for the sorption of MB on cedar sawdust in fixed-bed columns (i.e.,  $0.142\text{--}0.240 \text{ L mmol min}^{-1}$ ) [83] or synthetic polymers (i.e.,  $0.20\text{--}0.64 \text{ L mmol min}^{-1}$ ) [84]. The equalization of Eq. (6b) to 0 allows determining the  $H_0$  value (critical bed height); the value is close to  $0.56 \text{ cm}$ . This means that the transfer zone is relatively limited and is not controlling the mass transfer of the dye in the fixed-bed. Fig. S8 shows the determination of the parameters of the Yoon-Nelson model, while Fig. S9 compares the experimental profiles with their relevant modeling. The Yoon-Nelson equation remarkably fits the breakthrough profiles, with the notable exception of the exhaustion zone, which is over-estimated (requiring longer times or higher volumes, compared with practical application) (Table S3). From Eq. (6b), considering the time  $t_{0.5}$  corresponding to half-reduction of initial concentration ( $C_{out} = 0.5 C_0$ ), the right term in the equation cancels out; the plot of  $t_{0.5}$  vs.  $\zeta = H / (C_0 \times u)$  gives a straight line (Fig. S10). The slope corresponds to  $N_0$ , the value of the sorption capacity at half-exhaustion:  $481.5 \text{ mmol L}^{-1}$ ; i.e.,  $0.924 \text{ mmol MB g}^{-1}$ . This value may be compared with the calculated value of the sorption capacity for  $C_{eq}$ :  $0.6125 \text{ mmol MB L}^{-1}$ ;  $1.022 \text{ mmol MB g}^{-1}$ . The loss compared to this theoretical sorption capacity is less than 10% (i.e., much closer than the

loss observed for the breakthrough time, see above).

The BDST application to saturation time ( $t_s$ ) for varying column height is represented in Fig. S11. The  $k_{BDST}$  value is close to  $0.0222 \text{ L mmol}^{-1}$ . On the other side, the  $N_0$  sorption capacity at saturation of the fixed-bed tends to  $646 \text{ mmol L}^{-1}$ . Taking into account the apparent volumetric density of the bed, the sorption capacity reaches  $1.24 \text{ mmol MB g}^{-1}$ ; this is consistent with the maximum experimental sorption capacity of 2-MBI@Chit (i.e.,  $1.28 \text{ mmol MB g}^{-1}$ , Table 2). This also means that all the reactive groups remain accessible in dynamic mode. For each of the tested applications of the BDST model, the straight lines do not pass through the origin; Al-Degs et al. [46] reported that this may be explained by the combination of different rate-limiting steps.

### 3.3. Application to MB-spiked industrial effluent

To evaluate the impact of the complexity of the solution on MB sorption performance, the sorption efficiency and sorption capacity are compared in spiked solutions prepared with either tap water (see Table S4 for composition) or seawater for different dye concentrations (Fig. 9). The sorption capacity linearly increases with initial dye concentration in tap water, while for seawater a slope break is observed at  $C_0$ :  $0.0625 \text{ mmol MB L}^{-1}$  with a loss in sorption capacities of 4.7% at the lowest dye concentration (i.e.,  $0.0314 \text{ mmol MB L}^{-1}$ ). At higher dye concentration, the loss remains almost constant (in the range 15.5–19.8%). Despite the much complex composition of seawater with high concentrations of NaCl and other salts, the loss in sorption performance is relatively limited. This is consistent with the observations collected on the effect of NaCl concentration on MB sorption from synthetic solutions (Section 3.2.3.). The sorption efficiency (SE) in tap water varies between 93.4% and 83.9%. In the case of seawater, the SE decreases from 88.7% (at low concentration) to 70.7–72% at higher dye concentrations. These trends are consistent with similar observations reported by Ates and Oymak [85] for the sorption of MB from tap water and seawater using biochar produced from persimmon fruit peel (rich in tannins). Under selected experimental conditions, the loss in removal

**Fig. 9.** Treatment of MB-spiked tap water (TW) and seawater (SW) using 2-MBI@Chit – effect of MB concentration on sorption capacity and sorption efficiency (pH 9.3; SD:  $1.5 \text{ g L}^{-1}$ ; Time: 90 min; v-200 rpm).

efficiency between seawater and tap water reached 5.9% (at low dye concentration) and 19.5% (for higher concentration range). The remarkable stability in sorption performance, including in such complex solutions as seawater, confirms the potential interest of 2-MBI@Chit for wastewater treatment.

#### 4. Conclusions

Methylene blue shows a high affinity for 2-MBI@Chit. Different mechanisms (identified by FTIR spectroscopy and the study of pH effect) may be involved in the removal of the dye, depending on the pH, including:  $n-\pi$  interaction, dipole-dipole H bonding, H bonding, and/or electrostatic interaction.

Optimum sorption occurs at pH 9.3, with a sorbent dosage close to  $1.5 \text{ g L}^{-1}$  and under an agitation speed of 200 rpm (to reduce the resistance to film diffusion). The resistance to intraparticle diffusion plays a non-negligible role in the control of uptake kinetics; although, the pseudo-first order rate equation fits well the experimental profile. The sorption isotherms are fitted by the Langmuir equation; the sorption is slightly endothermic. The sorption capacities are weakly affected by the presence of NaCl (up to  $45 \text{ g L}^{-1}$ ). This property is confirmed by the evaluation of sorption performance in complex MB-spiked solutions (including seawater).

The efficiency of dye desorption reaches 94% using 0.8 M HCl and the sorbent maintains remarkable stability in sorption after five successive cycles of sorption/desorption: loss does not exceed 5% at the fifth cycle.

The breakthrough curves are fitted by the Yoon–Nelson model. The flow rate does not significantly change the slope of the breakthrough curve while increasing the mass of sorbent tends to decrease this slope. The sorption capacities at saturation of the bed are consistent with the sorption capacities collected from the Langmuir equation.

These remarkable properties (summarized by high relative sorption capacities, fast kinetics, high stability at recycling and in the presence of high salinities) make this sorbent highly promising for the recovery of methylene blue (emblematic example of industrial cationic dyes).
